

# Histogramming On A Reconfigurable Mesh Computer\*

*Jing-Fu Jenq*      *Sartaj Sahni*  
University of Minnesota      and      University of Florida

## Abstract

We develop reconfigurable mesh (RMESH) algorithms for window broadcasting, data shifts, and consecutive sum. These are then used to develop efficient algorithms to compute the histogram of an image and to perform histogram modification. The histogram of an  $N \times N$  image is computed by an  $N \times N$  RMESH in  $O(\sqrt{B} \log_{\sqrt{B}}(N/\sqrt{B}))$  for  $B < N$ ,  $O(\sqrt{N})$  for  $B = N$ , and  $O(\sqrt{B})$  for  $B > N$ .  $B$  is the number of gray scale values. Histogram modification is done in  $O(\sqrt{N})$  time by an  $N \times N$  RMESH.

## Keywords and Phrases

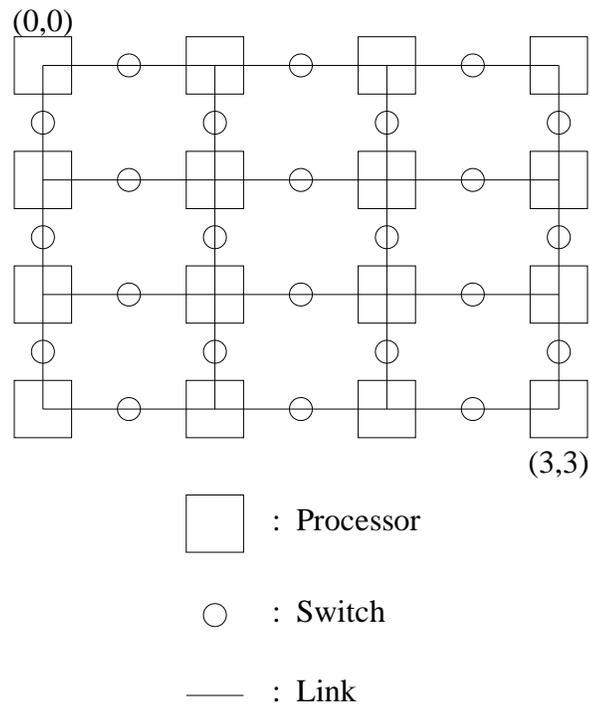

reconfigurable mesh computer, parallel algorithms, image processing, histogram.

## 1 Introduction

Miller, Prasanna Kumar, Resis and Stout [MILL88abc] have proposed a variant of a mesh connected parallel computer. This variant, called a reconfigurable mesh with buses (RMESH), employs a reconfigurable bus to connect together all processors. Figure 1 shows a 4×4 RMESH. By opening some of the switches, the bus may be reconfigured into smaller buses that connect only a subset of the processors.

**Figure 1** 4×4 RMESH

---

The important features of an RMESH are [MILL88abc]:

- 1 An  $N \times M$  RMESH is a 2-dimensional mesh connected array of processing elements (PEs). Each PE in the RMESH is connected to a broadcast bus which is itself constructed as an  $N \times M$  grid. The PEs are connected to the bus at the intersections of the grid. Each processor has up to four bus switches (Figure 1) that are software controlled and that can be used to reconfigure the bus into subbuses. The ID of each PE is a pair  $(i, j)$  where  $i$  is the row index

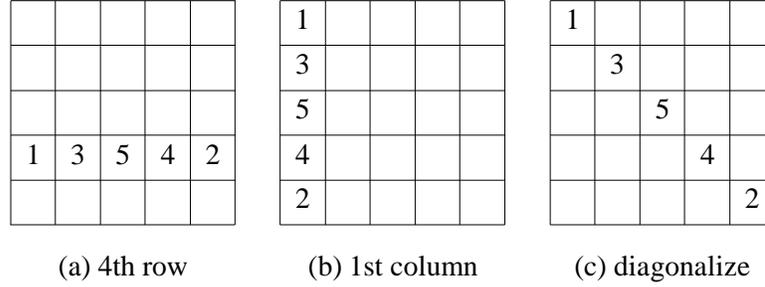

and  $j$  is the column index. The ID of the upper left corner PE is  $(0,0)$  and that of the lower right one is  $(N-1,M-1)$ .

- 2 The up to four switches associated with a PE are labeled E (east), W (west), S (south) and N (north). Notice that the east (west, north, south) switch of a PE is also the west (east, south, north) switch of the PE (if any) on its right (left, top, bottom). Two PEs can simultaneously set (connect, close) or unset (disconnect, open) a particular switch as long as the settings do not conflict. The broadcast bus can be subdivided into subbuses by opening (disconnecting) some of the switches.
- 3 Only one processor can put data onto a given sub bus at any time
- 4 In unit time, data put on a subbus can be read by every PE connected to it. If a PE is to broadcast a value in register  $I$  to all of the PEs on its subbus, then it uses the command `broadcast(I)`.
- 5 To read the content of the broadcast bus into a register  $R$  the statement `R := content(bus)` is used.
- 6 Row buses are formed if each processor disconnects (opens) its S switch and connects (closes) its E switch. Column buses are formed by disconnecting the E switches and connecting the S switches.
- 7 Diagonalize a row (column) of elements is a command to move the specific row (column) elements to the diagonal position of a specified window which contains that row (column). This is illustrated in Figure 2.

In Section 2, we develop RMESH algorithms for window broadcasting, data shift, and consecutive sum. In this section, we also state known results for some other data manipulation operations. These are used in Section 3 for our histogramming and histogram modification algorithms.

## 2 Basic Data Manipulation Operations

In this section we define several data manipulation algorithms for RMESH multicomputers. These are used in the next section to develop algorithms for histogramming and histogram modification.

---

### 2.1 Window Broadcast

The data to be broadcast is initially in the  $A$  variable of the PEs in the top left  $w \times w$  submesh. These PEs have ID  $(0,0) .. (w-1,w-1)$ . The data is to tile the whole mesh in such a way that  $A(i,j) = A(i \bmod w, j \bmod w)$  ( $A(i,j)$  denotes register  $A$  of the PE with ID  $(i,j)$ ). The algorithm for this is given in Figure 3. Its complexity is  $O(w)$  and is independent of the size of the RMESH.

### 2.2 Prefix Sum

Assume that  $N^2$  values  $A_0, A_1, \dots, A_{N^2-1}$  are initially distributed in the  $A$  variables of an  $N \times N$  RMESH such that  $A(i,j) = A_{iN+j}$ ,  $0 \leq i, j < N$ . PE  $(i,j)$  is to compute a value  $Sum(i,j)$  such that

$$Sum(i,j) = \sum_{k=0}^{iN+j} A_k, \quad 0 \leq i, j < N$$

An  $O(\log N)$  algorithm for this is given in [MILL88a].

### 2.3 Data Sum

Initially, each PE of the  $N \times N$  RMESH has an  $A$  value. Each PE is to sum up the  $A$  values of all the  $N^2$  PEs and put the result in its  $B$  variable. I.e., following the data sum operation we have :

$$B(i,j) = \sum_{k=0}^{N-1} \sum_{l=0}^{N-1} A(k,l), \quad 0 \leq i, j < N$$

---

```

procedure WindowBroadcast( $A, w$ );
{ broadcast the  $A$  values in the upper left  $w \times w$  submesh }
begin
  for  $j := 0$  to  $w-1$  do { broadcast column  $j$  of the submesh }
    begin
      diagonalize the  $A$  variables in column  $j$  of the  $w \times w$  submesh so that
       $B(i, i) = A(i, j), 0 \leq i < w$ ;
      set switches to form column buses;
       $PE(i, i)$  broadcasts its  $B$  value on column bus  $i, 0 \leq i < w$ ;
       $B(k, k \bmod w) := \text{content}(\text{bus}), 0 \leq k < N$ ;
      set switches to form row buses;
       $PE(k, k \bmod w)$  broadcasts its  $B$  value on its row bus,  $0 \leq k < N$ ;
       $A(k, i) := \text{content}(\text{bus})$  for  $i \bmod w = j$ , and  $0 \leq k < N$ ;
    end;
  end;

```

**Figure 3** Window broadcast

---

This can be done in  $O(\log N)$  time by first performing a prefix sum [MILL88a] and then having PE  $(N-1, N-1)$  broadcast  $Sum(N-1, N-1)$  to the remaining PEs in the RMESH. For this, all switches can be closed.

## 2.4 Shift

Each PE has data in its  $A$  variable that is to be shifted to the  $B$  variable of a processor that is  $s, s > 0$ , units to the right but on the same row. Following the shift, we have

$$B(i, j) = \begin{cases} \text{null} & j < s \\ A(i, j-s), & j \geq s \end{cases}$$

A circular shift variant of the above shift requires

$$B(i,j) = A(i, (j-s) \bmod N)$$

Let us examine the first variant first. This can be done in  $O(s)$  time by dividing the send and receive processor pairs  $((i, j-s), (i,j))$  into  $s+1$  equivalence classes as below:

$$\text{class } k = \{((i,j-s), (i,j)) \mid (j-s) \bmod (s+1) = k\}$$

The send and receive pairs in each class can be connected by disjoint buses and so we can accomplish the shift of the data in the send processors of each class in  $O(1)$  time. In  $O(s)$  time all the classes can be handled. The algorithm is given in Figure 4. The number of broadcasts is  $s+1$ . The procedure is easily extended to handle the case of left shifts. Assume that  $s < 0$  denotes a left shift by  $s$  units on the same row. This can also be done with  $s+1$  broadcasts.

---

```

procedure Shift(s,A,B)
{ Shift from  $A(i,j)$  to  $B(i,j+s)$ ,  $s > 0$  }
begin
  All PEs disconnect their N and S switches;
  for  $k := 0$  to  $s$  do { shift class  $k$  }
  begin
    PE( $i,j$ ) disconnects its E switch if  $(j-s) \bmod (s+1) = k$ ;
    PE( $i,j$ ) disconnects its W switch and broadcasts
       $A(i,j)$  if  $j \bmod (s+1) = k$ ;
     $B(i,j) := \text{content}(\text{bus})$  for every PE( $i,j$ ) with  $(j-s) \bmod (s+1) = k$ ;
  end;
end;

```

**Figure 4** Shifting by  $s, s > 0$

---

A circular shift of  $s$  can be done in  $O(s)$  time by first performing an ordinary shift of  $s$  and then shifting  $A(i, N-s), \dots, A(i, N-1)$  left by  $N-s$ . The latter shift can be done by first shifting  $A(i, N-s)$ , then  $A(i, N-s+1), \dots$ , and finally  $A(i, N-1)$ . The exact number of broadcasts is  $2s+1$ .

Circular shifts of  $s$ ,  $s > N/2$  can be accomplished more efficiently by performing a shift of  $-(N-s)$  instead. For  $s \leq N/2$ , we observe that data from PEs  $(i, 0), (i, 1), \dots, (i, s-1)$  need to be sent to PEs  $(i, s), (i, s+1), \dots, (i, 2s-1)$ , respectively. So, by limiting the data movement to within rows,  $s$  pieces of data need to use the bus segment between PE  $(i, s-1)$  and  $(i, s)$ . This takes  $O(s)$  time. If only the data on one row of the  $N \times N$  RMESH is to be shifted, the shifting can be done in  $O(1)$  time by using each row to shift one of the elements. The circular shift operation can be extended to shift in  $1 \times W$  row windows or  $W \times 1$  column windows. Let *RowCircularShift*  $(A, s, W)$  and *ColumnCircularShift*  $(A, s, W)$ , respectively, be procedures that shift the  $A$  values by  $s$  units in windows of size  $1 \times W$  and  $W \times 1$ . Let  $A^{in}$  and  $A^f$ , respectively, denote the initial and final values of  $A$ . Then, for *ColumnCircularShift* we have

$$A^{in}(i, j) = A^f(q, j)$$

where PEs  $(i, j)$  and  $(q, j)$  are, respectively, the  $a = i \bmod W$ 'th and  $b = q \bmod W$ 'th PEs in the same  $W \times 1$  column window and  $b = (a - s) \bmod W$ . The strategy of Figure 4 is easily extended so that *RowCircularShift* and *ColumnCircularShift* are done using  $2s + 1$  broadcasts.

## 2.5 Consecutive Sum

Assume that an  $N \times N$  RMESH is tiled by  $1 \times M$  blocks ( $M$  divides  $N$ ) in a natural manner with no blocks overlapping. So, processor  $(i, j)$  is the  $j \bmod M$ 'th processor in its block. Each processor  $(i, j)$  of the RMESH has an array  $X[0..M-1](i, j)$  of values. If  $j \bmod M = q$ , then PE  $(i, j)$  is to compute  $S(i, j)$  such that

$$S(i, j) = \sum_{r=0}^{M-1} X[q](i, (j \text{ div } M) * M + r)$$

That is, the  $q$ 'th processor in each block sums the  $q$ 'th  $X$  value of the processors in its block. The consecutive sum operation is performed by having each PE in a  $1 \times M$  block initiate a token that will accumulate the desired sum for the processor to its right and in its block. More specifically, the token generated by the  $q$ 'th PE in a block will compute the sum for the  $(q+1) \bmod M$ 'th PE in the block,  $0 \leq q < M$ . The tokens are shifted left circularly within their  $1 \times M$  block until each token has visited each PE in its block and arrived at its destination PE. The algorithm is given in Figure 5. The number of broadcasts is  $3M-3$  as each row circular shift of -1 takes 3 broadcasts.

---

```

procedure ConsecutiveSum ( $X, S, M$ );
{ Consecutive Sum of X in  $1 \times M$  blocks }
begin
   $S(i, j) := X[(j \bmod M) + 1 \bmod M](i, j), 0 \leq i, j < N$ ;
  for  $k := 2$  to  $M$  do
    begin
      { circularly shift  $S$  in  $1 \times M$  blocks and add terms }
      RowCircularShift ( $S, M, -1$ )
       $S(i, j) := S(i, j) + X[(j \bmod M) + k \bmod M](i, j), 0 \leq i, j < N$ ;
    end;
  end;

```

**Figure 5** Consecutive sums in  $1 \times M$  blocks

## 2.6 Sorting

$N^2$  elements, one per processor, can be sorted in  $O(N)$  time on an  $N \times N$  RMESH by simulating the  $O(N)$  sorting algorithm for ordinary mesh computers [NASS79]. That  $O(N)$  is optimal for an RMESH can be seen by considering the amount of data that might need to cross the boundary between the left  $N/2$  columns and the right  $N/2$  columns. This is  $N^2/2$  in the worst case. The bandwidth of this boundary is  $N$ . Hence  $O(N)$  time is needed to accomplish this data transfer. Miller et al. [MILL88a] present an  $O(\log N)$  sorting algorithm for the case when  $N$  elements are to be sorted on an RMESH with  $N^2$  processors. The initial and final configuration has the data in row 0 of the  $N \times N$  RMESH.

## 2.7 RAR And RAW

The random access read (RAR) and random access write (RAW) operations are defined in [NASS81]. In a RAR each PE has a read address associated with it. This is the address of the PE whose  $A$  variable it wishes to read. In a RAW each PE has a write address which is the address of the PE to which it wishes to send the value of its  $A$  variable. Conflicts may be resolved arbitrarily. Miller et al. [MILL88a] have developed RMESH algorithms for RARs and RAWs. When  $k$  data items are to be moved in the RAR or RAW, their algorithm takes  $O(\sqrt{k} + \log N)$  time,  $k \leq N^2$ . If the number of source and destination processors in each  $k \times k$  block of PEs is  $O(k)$ ,  $1 \leq k \leq N$  then their algorithm takes  $O(\log N)$  time.

## 3 Histograms

Let  $I[0..N-1, 0..N-1]$  be an  $N \times N$  digitized image with  $I[i, j]$  being the gray scale value of the pixel  $[i, j]$ . Let  $B$  be the range in gray scale values of the  $N^2$  pixels. So,  $0 \leq I[i, j] < B$ ,  $0 \leq i, j < N$ . The *histogram* of  $I$  is a vector  $H$  such that

$$H[a] = |\{[i, j] \mid I[i, j] = a, 0 \leq i, j < N\}|$$

I.e.,  $H[a]$  is the number of pixels that have the gray value  $a$ . The histogram of an image has applications in image enhancement and segmentation.

Several parallel algorithms to compute the histogram have been proposed in the literature. Siegel et al. [SIEG81] develop an algorithm for a  $p$  processor,  $p \leq N^2$ , PASM muticomputer while Yasrebi and Browne [YASR83] do so for the TRAC multicomputer. Grinberg, Nudd, and Etchells [GRIN84] consider the computation of  $H$  on an  $N^2$  processor cellular machine called the 3-D machine. The resulting algorithm has time complexity  $O(N)$ . The histogram,  $H$ , is easily computed in  $O(N^2)$  time on a serial single processor computer. This is optimal for such a computer as each of the  $N^2$  pixels needs to be examined and such a computer can examine only one pixel at any time. On a parallel computer with  $N^2$  processors,  $H$  can be computed in the time needed to sort  $N^2$  elements. The strategy for this is given in Figure 6. The processors are indexed  $0..N^2-1$  and the initial configuration has  $I(iN+j) = I[i, j]$ ,  $0 \leq i, j < N$ . The final configuration has the nonzero entries of  $H$  computed in  $H(b).gray$  and  $H(b).value$ ,  $0 \leq b < k$  for some  $k \leq \min\{N^2, B\}$ . If  $H(a).gray = q$ , then  $H[q] = H(a).value$ .

Following the sort of step 1 the  $I$  values form a nondecreasing sequence. Step 2 identifies the end (tail) and start (head) of each subsequence of  $I$  that is comprised solely of equal gray values. The length of each such sequence is one of the nonzero entries in  $H$ . This length is

$O(\sqrt{B} + \log(N/B))$  time. Their algorithm assumes  $B \ll N$ .

In Section 4.1 we show how to compute  $H$  on an  $N^2$  processor RMESH in time less than that needed to sort  $N^2$  elements on an  $N \times N$  RMESH. This algorithm is for the case  $B < N^2$ . For  $B \geq N^2$ , the algorithm of Figure 6 may be used to compute  $H$  in  $O(N)$  time. Recall that  $N^2$  elements can be sorted on an  $N \times N$  RMESH in  $O(N)$  time. In Section 4.2 we develop an algorithm to do histogram modification on an  $N \times N$  RMESH.

### 3.1 Computing $H$

We shall develop two algorithms. One requires  $O(\sqrt{B})$  memory per processor and the other requires  $O(1)$ . The first of these uses fewer broadcast steps than does the second.

#### 3.1.1 $O(\sqrt{B})$ Memory Algorithm

First consider the case  $B = N$ . Initially, we have  $I(i,j) = I[i,j]$ ,  $0 \leq i,j < N$ . On termination, the  $H$  values are stored in column 0 of the RMESH. I.e.,  $H(i,0) = H[i]$ ,  $0 \leq i < N$ . Our strategy is to first have each  $\sqrt{N} \times \sqrt{N}$  (assume for simplicity that  $N$  is a perfect square) sub RMESH work independently and compute  $H$  for the  $\sqrt{N} \times \sqrt{N}$  portion of the image it contains. These  $\sqrt{N} \times \sqrt{N}$  sub RMESHs are obtained by a natural  $\sqrt{N} \times \sqrt{N}$  tiling of the  $N \times N$  RMESH. The sub RMESHs can work independently by simply disconnecting their boundary switches. Figure 7 shows a  $16 \times 16$  RMESH partitioned into 16  $4 \times 4$  sub RMESHs. Processors with the same label are in the same sub RMESH. Each  $\sqrt{N} \times \sqrt{N}$  sub RMESH has  $B = N$  processors. Each of these is to compute  $H[a]$  for exactly one value of  $a$ ,  $0 \leq a < B$ . Of course, the  $H$  value computed is only for the image partition contained in the sub RMESH. Processor  $(i,j)$  of a  $\sqrt{N} \times \sqrt{N}$  sub RMESH computes  $H[i+j\sqrt{N}]$ ,  $0 \leq i,j < \sqrt{N}$ . Figure 8 shows the  $H$  values to be computed by each processor of a  $4 \times 4$  sub RMESH.

In order to compute the  $H$ 's as described, each processor  $(i,j)$  of a sub RMESH first computes an array  $A[0..\sqrt{N}-1]$  of values where  $A[b](i,j)$  is the number of pixels in row  $i$  of the sub RMESH that have gray value equal to  $j\sqrt{N}+b$ ,  $0 \leq b < \sqrt{N}$ . This can be computed in  $O(\sqrt{N})$  time by obtaining the contribution of each of the  $\sqrt{N}$  columns in the sub RMESH in a different iteration. On iteration  $k$  (see Figure 9), column  $k$  of the sub RMESH broadcasts its  $I$  values along row buses that are confined to the sub RMESH. Each processor reads its row bus and determines if the  $I$  value read contributes to its  $A$  array. Note that the  $A$  array of the  $(i,j)$ 'th PE of a sub RMESH accounts for gray values in the range  $j\sqrt{N}$  through  $(j+1)\sqrt{N}-1$ . If so, the appropriate  $A$  value is to be updated. Let  $T(i,j)$  be the  $I$  value read by the  $(i,j)$ 'th processor of the sub RMESH.

**Figure 7** Partitioning a 16×16 RMESH into 4×4 sub RMESHs

---

To contribute to the  $A$  array of this processor,  $T$  must be such that  $j\sqrt{N} \leq T(i,j) < (j+1)\sqrt{N}$ . If this is so, then  $A[T(i,j)-j\sqrt{N}]$  corresponds to the gray value  $T(i,j)$ .

Once the  $A$  arrays have been computed, the  $H$  values as given in Figure 8 can be computed in  $O(\sqrt{N})$  time by using the consecutive sum operation of Section 2. Following this, each processor of the  $N \times N$  RMESH contains in  $H$  a partial histogram value. The situation for a 16×16 RMESH is shown in Figure 10. We need to add together all partial values that contribute to the same histogram value. This is done by first adding along columns. The  $N$  processors in each column contain partial values for exactly  $\sqrt{N}$  different histogram values. In fact, the column  $j$   $H$  values so far computed contribute towards  $H[(j \bmod \sqrt{N})\sqrt{N}], \dots, H[(j \bmod \sqrt{N})\sqrt{N} + \sqrt{N}-1]$ .

H[3]	H[7]	H[11]	H[15]

**Figure 8** The  $H[a]$  computed by each PE in a  $4 \times 4$  sub RMESH

---

For each column  $j$ , the  $H$  values that contribute to the same histogram value  $H[a]$  are added together. Note that  $(j \bmod \sqrt{N})\sqrt{N} \leq a < (j \bmod \sqrt{N})\sqrt{N} + \sqrt{N}$  and that the  $H$  value in PE  $(i, j)$  contributes to  $H[b]$  where  $b = (j \bmod \sqrt{N})\sqrt{N} + i \bmod \sqrt{N}$ . The additions can be done in  $O(\sqrt{N})$  time by pipelining the  $\sqrt{N}$  different sums to be computed in each column as in Figure 11. Each processor has two Boolean variables *receive* and *send*. *receive* is true for each processor that is to receive a value and *send* is true for each processor that is to send one. Each column consists of  $\sqrt{N}$  blocks each of size  $\sqrt{N}$  and the  $i$ 'th data in each block is to be summed,  $0 \leq i < \sqrt{N}$ . This is accomplished by shifting data up the column in a pipelined manner. In the first iteration of the **for** loop of Figure 11, the 0'th PE of the bottommost block sends its data to the corresponding PE in the block above it; in the second iteration, the 0'th PE of the next to bottom block and the 1st PE of the bottommost block send their data to corresponding PEs one block up; in the third iteration, the 0'th PE of the second to bottom block, the 1st PE of the next to bottom block, and the 2nd PE of the bottom block send their data up; and so on.

The algorithm of Figure 11 saves the results in the top  $\sqrt{N}$  processors of each column. However, we require that the  $\sqrt{N}$  sums computed for column  $j$  be left in the  $R$  variables of the

        if  $j\sqrt{N} \leq T(i,j) < (j+1)\sqrt{N}$  { $T$  is a value for PE  $(i,j)$ }
        then  $A[T(i,j)-j\sqrt{N}](i,j) := A[T(i,j)-j\sqrt{N}](i,j)+1;$ 
        end;

```

**Figure 9** Computing  $A$  in a  $\sqrt{N} \times \sqrt{N}$  sub RMESH

---

processors  $(i,j)$  such that  $(j \bmod \sqrt{N})\sqrt{N} \leq i < (j \bmod \sqrt{N})\sqrt{N} + \sqrt{N}$ . The desired configuration for  $R$  can be obtained by doing a window broadcast down the columns and then zeroing out the  $R$  values in the processors that don't need these values.

To obtain the histogram values we now need to sum the  $R$  values on each row. This is easily done in  $O(\log N)$  time using the data sum operation. The overall complexity of our histogram algorithm for the case  $N = B$  is therefore  $O(\sqrt{N})$ .

Next, consider the case  $B < N$ . For simplicity, assume that  $\sqrt{B}$  divides  $N$ . Instead of tiling the  $N \times N$  mesh with  $\sqrt{N} \times \sqrt{N}$  blocks as for the case when  $B = N$ , this time use  $\sqrt{B} \times \sqrt{B}$  blocks and proceed as for the case  $B = N$ . The **for** loop of Step 3 of Figure 9 is now to be run only for  $k$  equal to 0 through  $\sqrt{B}-1$ , and each processor accumulates only  $\sqrt{B}$   $A$  values. The computation of  $A$  takes  $O(\sqrt{B})$  time. The consecutive sum operation to get the partial histogram values also takes  $O(\sqrt{B})$  time as it is confined to sub columns of size  $\sqrt{B}$ . Summing up partial histogram values along columns takes  $O(\sqrt{B} \log_{\sqrt{B}}(N/\sqrt{B}))$  time. The results of the column sum process are

---

```

procedure ColumnSum;
begin
  connect N switch and disconnect E switch; { create column buses }
  receive := false;
  send := false;
  b := i div  $\sqrt{N}$ ; { i is row index of PE, b is block number }
  for k := 0 to  $2\sqrt{N} - 3$  do
    begin
      { Activate a receive in a new block }
      if  $\sqrt{N} - b - 2 = k$ 
        then begin receive := true; l := 0; end;
      { Activate a send from a new block }
      if  $\sqrt{N} - b - 1 = k$ 
        then begin send := true; m := 0; end;
      { Set up sends }
      if send then begin
        if (i mod  $\sqrt{N} = m$ ) { m'th PE in block is to send }
          then begin
            disconnect S switch;
            broadcast H;
            send := false;
            connect S switch;
          end
          m := m + 1; { next one to send in block }
        end;
      { Set up receives }
      if receive then begin
        if (i mod  $\sqrt{N} = l$ ) { l'th PE in block is to receive }
          then begin
            disconnect N switch;
            t := content(bus);
            H := H + t;
            connect N switch;
            receive := false;
          end
          l := l + 1; { next one to receive in block }
        end
      end
    end
  end

**Figure 11** Summing up  $H$  values along columns

left in rows 0 through  $B-1$  of the RMESH. These rows need to perform a row sum operation. Since each row has  $N/\sqrt{B}$  values to be summed, the time needed is  $O(\log N/\sqrt{B})$ . The overall complexity becomes  $O(\sqrt{B} \log_{\sqrt{B}}(N/\sqrt{B}))$ .

Next, suppose  $N < B < N^2$ . For simplicity, assume that  $\sqrt{B}$  divides  $N$ . Use  $\sqrt{B} \times \sqrt{B}$  tiles as above. The final configuration, this time, has the histogram values in the top left  $\sqrt{B} \times \sqrt{B}$  sub RMESH (this is necessary as  $B > N$  and the histogram array cannot fit in a single column of the RMESH, one element per processor). The modifications to the case  $N < B < N^2$  are straightforward. The complexity is  $O(\sqrt{B})$ . When  $B \geq N^2$ , we can use the algorithm of Figure 6 to compute  $H$  in  $O(N)$  time. So, except when  $B \geq N^2$ , we can compute  $H$  on an  $N \times N$  RMESH in less time than it takes to sort  $N^2$  elements on such an RMESH. Notice that when  $B \geq N^2$  only  $O(1)$  memory per processor is needed.

### 3.1.2 $O(1)$ Memory Algorithm

We explicitly consider only the case  $B = N$ . The algorithm differs from that for the  $O(\sqrt{B})$  memory case only in the way the partial histogram values  $H$  are computed. This time, we sort the  $I$  values in each  $\sqrt{N} \times \sqrt{N}$  sub RMESH, determine the head and tail of each sequence of equal  $I$  values, then determine the length of each such sub sequence using two concentrations as in Figure 6. All of this takes  $O(\sqrt{N})$  time on a  $\sqrt{N} \times \sqrt{N}$  RMESH. Next a random access write [NASS81] is used to route these  $H$  values to the appropriate processors so as to get the configuration of  $H$  values that results from Figure 9 and a consecutive sum. This also takes  $O(\sqrt{N})$  time. A column sum and row sum, as for the case of the  $O(\sqrt{B})$  memory algorithm, is needed to complete the computation. Since these summing operations take  $O(\sqrt{N})$  time, the overall complexity becomes  $O(\sqrt{N})$ . The sort and random access write operations require many more broadcast steps than used in Figure 9 and in a consecutive sum. Hence the  $O(1)$  memory algorithm is less efficient, in terms of time, than the  $O(\sqrt{B})$  memory algorithm.

### 3.2 Histogram Modification

One of the operations commonly performed following the computation of the histogram of an image is histogram modification. In this the original gray values of the pixels are mapped to new gray values according to some function  $f(OldGrayValue) \rightarrow NewGrayValue$ ,  $0 \leq OldGrayValue < B$  [LIM84]. This mapping is done in such a way that the new histogram approximates a desired distribution. Histogram modification is often done to improve the utilization of the available range of the gray scale and enhance the contrast of the image. For example, the histogram of an underexposed photograph is biased towards the darker gray levels.

Histogram modification is done in two steps:

- 1) Compute  $f$
- 2) Update the gray values according to  $f$

We consider two cases for the computation of  $f$ . In both we limit our discussion to the case  $B = N$ . Our algorithms are easily extended to other values of  $B$ . The two cases we consider are: histogram flattening and histogram modification by a prespecified distribution (e.g., normal distribution).

In histogram flattening (also known as histogram equalization) [PAVL82], the function  $f$  is obtained in the following way. Let  $S[i] = \sum_{j=0}^i H[j]$ ,  $0 \leq i < B$ , i.e.,  $S[0..N-1]$  gives the prefix sums of the histogram values.  $f(i)$  is defined as :

$$f(i) = \lfloor S[i]/N \rfloor, 0 \leq i < N$$

$$\text{or } f(i) = \lfloor (S[i] + S[i-1])/(2N) \rfloor, 0 \leq i < N$$

Regardless of which definition is used, we can easily compute  $f$  on an  $N \times N$  RMESH in  $O(\log N)$  time. Since the algorithm of Section 4.1 leaves  $H$  in column 0 of the RMESH, the computation of  $f$  involves a prefix sum of  $H$  values in column 0, followed by a possible shift by 1 of the prefix sum values (in case the second definition of  $f$  is used), and then some simple arithmetic. The prefix sum takes  $O(\log N)$  time and the shift  $O(1)$  time. The function values  $f$  are left in column 0 of the RMESH. In the case of histogram modification by a prespecified distribution,  $f$  is computed by first obtaining the prefix sums  $y_0, y_1, \dots, y_{B-1}$  of the desired distribution. Let  $s_0, s_1, \dots, s_{B-1}$  be the prefix sums of the histogram  $H$ . For any  $i$ ,  $0 \leq i < B$ ,  $f(i)$  is defined to be an integer  $k$  such that  $|y_k - s_i|$  is minimum over all  $k$ . We assume that ties are broken by picking the smallest  $k$  which minimizes  $|y_k - s_i|$ . For the computation of  $f$  we assume an initial condition in which the  $H$  values are stored, one value per processor, in column 0 of the  $N \times N$  RMESH

and the distribution values are stored, one value per processor, in row 0 of the RMESH. The algorithm to compute  $f$  is given in Figure 12. It is self explanatory and its complexity is  $O(\log N)$ . The correctness of step 7 follows from the observation that since the  $y_i$ 's form a monotonically increasing sequence, the  $d$ 's form a bitonic sequence.

Now that we have seen how to compute  $f$ , we can consider the updating of the gray values as prescribed by  $f$ . The algorithm for this is given in Figure 12. In step 1 each processor accumulates  $\sqrt{N}$   $f$  values. Specifically, if PE  $(i,j)$  is the  $(a,b)$ 'th processor in its  $\sqrt{N} \times \sqrt{N}$  sub RMESH, then  $U[k](i,j) = f(b\sqrt{N} + k)$ ,  $0 \leq k < \sqrt{N}$ . So, the  $U$  arrays in all processors in the same column of the  $N \times N$  RMESH are the same. Processors in column  $j$  will contain, in their  $U$  array, the values  $f(l)$ ,  $(j \bmod \sqrt{N})\sqrt{N} \leq l < (j \bmod \sqrt{N})\sqrt{N} + \sqrt{N}$ . Specifically, we require

$$U[k](i,j) = f((j \bmod \sqrt{N})\sqrt{N} + k), 0 \leq k < \sqrt{N}, 0 \leq i, j < N.$$

Notice that the range of  $U$  values in a processor corresponds to the range of  $A$  values computed in Figure 9. The actual updating of the gray values is done in step 2 of Figure 12. The process is somewhat similar to that used to obtain the  $A$  array in Figure 9. The  $I$  values are updated by considering the pixels in each  $\sqrt{N} \times \sqrt{N}$  sub RMESH in column order. When the pixels in column  $k$  of the sub RMESHs are being considered, these pixels broadcast their gray values along row buses that are local to the sub RMESHs. The processors in each row of a sub RMESH contain the entire  $f$  function in their  $U$  arrays,  $\sqrt{N}$  values per processor. When a processor receives a gray value,  $V(i,j)$ , it determines if this value is included in its range of  $f$  values. The  $f$  value range in PE  $(i,j)$  is from  $(j \bmod \sqrt{N})\sqrt{N}$  through  $(j \bmod \sqrt{N})\sqrt{N} + \sqrt{N} - 1$ . If the gray value is in its range, PE  $(i,j)$  determines the new gray value corresponding to this old gray value. The new gray value is then broadcast back to the PE that originated the old gray value and the old value is finally updated by the new one.

The complexity of the algorithm of Figure 12 is readily seen to be  $O(\sqrt{N})$ .

#### 4 Conclusions

For the histogram problem we have developed an  $N \times N$  RMESH algorithm that is faster than sorting when the number,  $B$ , of gray scale values is less than  $N^2$ . The time complexity of this algorithm is  $O(\sqrt{B} \log_{\sqrt{B}}(N/\sqrt{B}))$  for  $B < N$ ,  $O(\sqrt{N})$  for  $B = N$ , and  $O(\sqrt{B})$  for  $B > N$ . The algorithm uses  $O(\sqrt{B})$  memory per processor. Another  $N \times N$  RMESH algorithm using  $O(1)$  memory per processor was also developed. This has complexity  $O(\sqrt{N})$  where  $N = B$ . Finally, we showed how histogram modification could be done on an  $N \times N$  RMESH in  $O(\sqrt{N})$  time.

- 
- Step 1** Prefix sum the distribution values in row 0 of the RMESH.  
The prefix sums are stored in  $y(0,j)$ ,  $0 \leq j < N$ .
- Step 2** Prefix sum the histogram values in column 0 of the RMESH.  
These sums are stored in  $s(i, 0)$ ,  $0 \leq i < N$ .
- Step 3** Set up column buses and broadcast the  $y(0,j)$  values,  $0 \leq j < N$ .  
 $y(i,j) := \text{content}(\text{bus}), 0 \leq i, j < N; \{y(i,j) = y_j\}$
- Step 4** Set up row buses and broadcast the  $s(i, 0)$  values,  $0 \leq i < N$ .  
 $s(i,j) := \text{content}(\text{bus}), 0 \leq i, j < N; \{s(i,j) = s_i\}$
- Step 5**  $d(i,j) := |y(i,j) - s(i,j)|$ ,  $0 \leq i, j < N$ .
- Step 6** Shift the  $d$  values left on rows by 1, the shifted values are in the  $e$  variables, I.e.,  $e(i,j) = d(i,j+1)$ ,  $0 \leq i < N$ ,  $0 \leq j < N-1$
- Step 7** **if**  $d(i,j) < e(i,j)$  **then** PE  $(i,j)$  disconnects its E switch  
and then broadcasts  $j$ ;  $0 \leq i < N$ ,  $0 \leq j < N-1$ ;  
PE  $(i,N-1)$  broadcasts  $N-1$ ,  $0 \leq i < N$ ;
- Step 8**  $f(i, 0) := \text{content}(\text{bus})$ ;
