# **Anomalies In Parallel Branch-and-Bound Algorithms\***

Ten-Hwang Lai+ and Sartaj Sahni University of Minnesota

#### **Abstract**

We consider the effects of parallelizing branch-and-bound algorithms by expanding several live nodes simultaneously. It is shown that it is quite possible for a parallel branch-and-bound algorithm using  $n_2$  processors to take more time than one using  $n_1$  processors even though  $n_1 < n_2$ . Furthermore, it is also possible to achieve speedups that are in excess of the ratio  $n_2/n_1$ . Experimental results with the 0/1-Knapsack and Traveling Salesperson problems are also presented.

# **Key Words and Phrases**

Parallel Algorithms, branch-and-bound, anomalous behavior.

#### 1. Introduction

Branch-and-bound is a popular algorithm design technique that has been successfully used in the solution of problems that arise in various fields (e.g., combinatorial optimization, artificial intelligence, etc.) [1, 9 - 15]. We shall briefly describe the branch-and-bound method as used in the solution of combinatorial optimization problems. Our terminology is from Horowiz and Sahni [10].

In a combinatorial optimization problem we are required to find a vector  $\mathbf{x} = (x_1, x_2, ..., x_n)$  that optimizes some criterion function  $\mathbf{f}(\mathbf{x})$  subject to a set C of constraints. This constraint set may be partitioned into two subsets: explicit and implicit. Implicit constraints specify how the  $x_i$ s must relate to each other. Two examples are:

$$1) \sum_{i=1}^{n} a_i x_i \le \mathbf{b}$$

2) 
$$a_1x_1^2 - a_2x_1x_2 + a_3x_3^4 = 6$$

Explicit constraints specify the range of values each  $x_i$  can take. For example:

1) 
$$x_i \in \{0, 1\}$$

2) 
$$x_i \ge 0$$

The set of vectors that satisfy the explicit constraints defines the *solution space*. In a branch-and-bound approach this solution space is organized as a graph which is usually a tree. This resulting organization is called a *state space graph (tree)*. All the state space graphs used in this paper are *trees*. So, we shall henceforth only refer to state space trees. Figure 1 shows a state space tree for the case n = 3 and  $x_i \in \{0, 1\}$ . The path from the root to some of the nodes (in this case the leaves) defines an element of the solution space. Nodes with this property are called *solution nodes*. Solution nodes that satisfy the implicit constraints are called *feasible solution nodes* or *answer nodes*. Answer nodes have been drawn as double circles in Figure 1. The *cost* of an answer node is the value of the criterion function at that node. In solving a combinatorial optimization problem we wish to find a *least cost answer node*.

For convenience we assume that we wish to minimize f(x). With every node N in the state space tree, we associate a value  $f_{\min}(N) = \min\{f(Q) : Q \text{ is a feasible solution node in the subtree N}\}$ . (If there exists no such Q, then let  $f_{\min}(N) = \infty$ .)

While there are several types of branch-and-bound algorithms, we shall be concerned only with the more popular *least cost branch-and-bound* (lcbb). In the context of maximization problems, this method has been referred to as *branching from the largest upper bound* (blubb) [6]. In this method a heuristic function g() with the following properties is used:

- (P1)  $g(N) \le f_{min}(N)$  for every node N in the state space tree.
- (P2) g(N) = f(N) for solution nodes representing feasible solutions (i.e., answer nodes).
- (P3)  $g(N) = \infty$  for solution nodes representing infeasible solutions.

Figure 1 A state space tree

(P4)  $g(N) \ge g(P)$  if N is a child of P.

g() is called a *bounding function*. lcbb generates the nodes in a state space tree using g(). A node that has been generated, can lead to a feasible solution, and whose children haven't yet been generated is called a *live node*. A list of live nodes is maintained (generally as a heap). In each iteration of the lcbb a live node, N, with least g() value is selected. This node is called the current *E-node*. If N is an answer node, it must be a least cost answer node. If N is not an answer node, its children are generated. Children that cannot lead to a least cost answer node (as determined by some heuristic) are discarded. The remaining children are added to the list of live nodes.

The problem of parallelizing lcbb has been studied earlier [2 - 5, 8, 16]. There are essentially three ways to introduce parallelism into lcbb:

- (1) Expand more than 1 E-node during each iteration.
- (2) Evaluate g() and determine feasibility in parallel.
- (3) Use parallelism in the selection of the next E-node(s).

Wah and Ma [16] exclusively consider (1) above (though they point out (2) and (3) as possible sources of parallelism). If p processors are available then  $q = \min\{p, \text{ number of live nodes}\}\$  live nodes are selected as the next set of E-nodes (these are the q live nodes with smallest g() values). Let  $g_{\min}$  be the least g value among these q nodes. If any of these E-nodes is an answer node and has g() value equal to  $g_{\min}$  then a least cost answer node has been found. Otherwise all q E-nodes are expanded (with one processor expanding exactly one E-node) and their children added to the list of live nodes. Each such expansion of q E-nodes counts as one iteration of the parallel lcbb. For any given problem instance and g, let I(p) denote the number of iterations needed when p processors are available. Intuition suggests that the following might be true about I(p):

(I1)  $I(n_1) \ge I(n_2)$  whenever  $n_1 < n_2$ 

(I2) 
$$\frac{I(n_1)}{I(n_2)} \le \frac{n_2}{n_1}$$

In Section 2, we show that neither of these two relations valid. Even if the g()s are restricted beyond (P1) - (P4), these relations do not hold. The experimental results provided in Section 3 do, however, show that (I1) and (I2) can be expected to hold "most" of the time. Some of the anomalies studied here have been observed earlier [4]. However, no formal study of these anomalies has been carried out earlier. It is also worth noting that Graham [6] has studied anomalies that arise in multiprocessor processing. His study, however, is not directly related to ours as it does not consider branch-and-bound algorithms.

Wah and Ma [16] experimented with the vertex cover problem using  $2^k$ ,  $0 \le k \le 6$  processor. Their results indicate that  $I(1)/I(p) \approx p$ . Our experiments with the 0/1-Knapsack and Traveling Salesperson problems indicate that  $I(1)/I(p) \approx p$  only for "small" values of p (say  $p \le 16$ ).

#### 2. Some Theorems For Parallel Branch-and-Bound

As remarked in the introduction, several anomalies occur when one parallelizes branch-and-bound algorithms by using several E-nodes at each iteration. In this section we establish these anomalies under varying constraints for the bounding function g(). First, it should be recalled that the g() functions typically used (eg. for the knapsack problem, traveling salesperson problem, etc. cf. [10]), in addition to satisfying properties P1-P4, satisfy the following property:

P5. Several nodes in the state space tree may have the same g() value. In fact, many nonsolution nodes may have a g() value equal to f\*, the value of an optimal solution. This is particularly true of nodes that are near ancestors of solution nodes.

In constructing example state space trees, we shall keep P1-P4 in mind. None of the trees constructed will violate P1-P4 and we shall not explictly make this point in further discussion. The first result we shall establish is that it is quite possible for a parallel branch-and-bound using  $n_2$  processors to perform much worse than one using a smaller number  $n_1$  of processors.

**Theorem 1**: Let  $n_1 < n_2$ . For any k > 0, there exists a problem instance such that  $kI(n_1) < I(n_2)$ . **Proof**: Consider a problem instance with the state space tree of Figure 2. All nonleaf nodes have the same g() value equal to  $f^*$ , the f value of the least cost answer node (node A). When  $n_1$  processors are available, one processor expands the root and generates its  $n_1 + 1$  children. Let us suppose that on iteration 2, the left  $n_1$  nodes on level 2 get expanded. Of the  $n_1$  children generated  $n_1 - 1$  get bounded and only one remains live. On iteration 3 the remaining live node on level 2 (B) and the one on level 3 are expanded. The level 3 node leads to the solution node and the algorithm terminates with  $I(n_1) = 3$ .

When  $n_2$  processors are available, the root is expanded on iteration 1 and all  $n_1 + 1$  live nodes from level 2 get expanded on iteration 2. The result is  $n_2 + 1$  live nodes on level 3. Of these, only  $n_2$  can be expanded on iteration 3. These  $n_2$  could well be the rightmost  $n_2$  nodes. And iterations 4, 5, ..., 3k could very well be limited to the rightmost subtree of the root. Finally in iteration 3k + 1, the least cost answer node a is generated. Hence,  $I(n_2) = 3k + 1$  and  $I(n_2) = I(n_2)$ .

In the above construction, all nodes have the same  $g(\ )$  value,  $f^*$ . While this might seem extreme, property P5 above states that it is not unusual for real g-functions to have a value  $f^*$  at many nodes. The example of Figure 2 does serve to illustrate why the use of additional processors may not always be rewarding. The use of an additional processor can lead to the development of a node N (such as node B of Figure 2) that looks "promising" and eventually diverts all or a significant number of the processors into its subtree. When fewer processors are used, the upper bound U at the time this "promising" node is to get expanded might be such that  $U \le g(N)$  and so N is not expanded when fewer processors are available. At this point, it is worth noting that Fox et al. [6] have observed that when several nodes have the same g() value, then some lcbb (or blubb, in their terminology) strategies are non-optimal. So, even in this case of a single processor, nodes with the same g() value create difficulties.

The proof of Theorem 1 hinges on the fact that g(N) may equal  $f^*$  for many nodes (independent of whether these nodes are least cost answer nodes or not). If we require the use of g-functions that can have the value  $f^*$  only for least cost answer nodes, then Theorem 1 is no longer valid for all combinations of  $n_1$  and  $n_2$ ,  $n_1 < n_2$ . In particular, if  $n_1 = 1$  then the use of more processors never increases the number of iterations (Theorem 2).

**Figure 2:** Instance for Theorem 1

*Definition*: A node N is *critical* iff  $g(N) < f^*$ .

**Theorem 2**: If  $g(N) \neq f^*$  whenever N is not a least cost answer node, then  $I(1) \geq I(n)$  for n > 1.

**Proof**: When the number of processors is 1, only critical nodes and least cost answer nodes can become E-nodes (as whenever an E-node is to be selected there is at least one node N with  $g(N) \le f^*$  in the list of live nodes). Furthermore, every critical node becomes an E-node by the time the branch-and-bound algorithm terminates. Hence, if the number of critical nodes is m, I(1) = m.

When n > 1 processors are available, some noncritical nodes may become E-nodes. However, at each iteration, at least one of the E-nodes must be a critical node. So,  $I(n) \le m$ . Hence,  $I(1) \ge I(n)$ .

When  $n_1 \neq 1$ , a degradation in performance is possible with  $n_2 > n_1$  even if we restrict the g()s as in Theorem 2.

**Theorem 3**: Assume that  $g(N) \neq f^*$  whenever N is not a least cost answer node. Let  $1 < n_1 < n_2$  and k > 0. There exists a problem instance such that  $I(n_1) + k \leq I(n_2)$ .

**Proof**: Figures 3(a) and 3(b) show two identical subtrees T. Assume that all nodes have the same g() value and are critical. The numbers inside each node give the iteration number in which that node becomes an E-node when  $n_1$  processors are used (Figure 3(a)) and when  $n_2$  processors are used (Figure 3(b)). Other evaluation orders are possible. However, the ones shown in Figures 3(a) and 3(b) will lead to a proof of this theorem.

We can construct a larger state space tree by connecting together k copies of T (Figure 3(c)). The B node of one copy connects to the A node (root) of the next. Each triangle in this figure represents a copy of T. The least cost answer node is the child of the B node of the last copy of T. It is clear that for the state space tree of Figure 3(c),  $I(n_1) = jk$  while  $I(n_2) = (j + 1)k$ . Hence,  $I(n_1) + k = I(n_2)$ .

The assumption that  $g(N) \neq f^*$  when N is not a least cost answer node is not too unrealistic as it is often possible to modify typical g() so that they satisfy this requirement. The example of Figure 3 has many nodes with the same g() value and so we might wonder what would happen if we restricted the g() so that only least cost answer nodes can have the same g() value. This restriction on g() is quite severe and, in practice, it is often not possible to guarantee that the g() in use satisfies this restriction. However, despite the severity of the restriction one cannot guarantee that there will be no degradation of performance using  $n_2$  processors when  $n_1 < n_2 < 2(n_1 - 1)$ . We have unfortunately been unable to extend our result of Theorem 4 to the case when  $n_2 \ge 2(n_1 - 1)$ . So, it is quite possible that no degradation is possible when the number of processors is (approximately) doubled and g() is restricted as above.

**Theorem 4**: Let  $n_1 < n_2 < 2(n_1 - 1)$  and let k > 0. There exists a g() and a problem instance that satisfy the following properties:

- (a)  $g(N_1) \neq g(N_2)$  unless both of  $N_1$  and  $N_2$  are least cost answer nodes.
- (b)  $I(n_1) + k \le I(n_2)$ .

**Proof**: Consider the state space tree of Figure 4(a). The number outside each node is its g() value while the number inside a node gives the iteration in which that node is the E-node when  $n_1$  processors are used. It takes  $n_1$  processors 4 iterations to get to and evaluate node B. When  $n_2$  processors are available,  $n_1 < n_2 < 2(n_1 - 1)$ , the iteration numbers are as given in Figure 4(b).

This time 5 iterations are needed. Combining k copies of this tree and setting the g() values in each copy to be different from those in other copies yields the tree of Figure 4(c). For this tree, we see that  $I(n_1) + k = I(n_2)$ .

The remaining results we shall establish in this section are concerned with the maximum improvement in performance one can get in going from  $n_1$  to  $n_2$  processors,  $n_1 < n_2$ . Generally, one would expect that the performance can increase by at most  $n_2/n_1$ . This is not true for branch-and-bound. In fact, Theorem 5 shows that using g()s that satisfy properties P1-P5, an unbounded improvement in performance is possible. The reason for this is much the same as for the possibility of an unbounded loss in performance. The additional processors might enable us to improve the upper bound quickly thereby curtailing the expansion of some of the nodes that might get expanded without these processors.

**Theorem 5**: Let  $n_1 < n_2$ . For any  $k > n_2/n_1$ , there exists a problem instance for which  $I(n_1)/I(n_2) \ge k > n_2/n_1$ .

**Proof**: Simply consider the state space tree of Figure 5(a). All nodes have the same g() value,  $f^*$ . Assume that when  $n_1$  processors are used, the  $n_1$  nodes at the left end of level i become Enodes on iteration i,  $2 \le i \le 2k$ . Hence,  $I(n_1) = 2k + 1$ . When  $n_2 > n_1$  processors are used,  $I(n_2) = 2$  (Figure 5(b)) and  $I(n_1)/I(n_2) > k$ .

As in the case of Theorem 2, we can show that if  $g(N) \neq f^*$  whenever N is not a least cost answer node, then  $I(1)/I(n) \leq n$ .

**Theorem 6**: Assume that  $g(N) \neq f^*$  whenever N is not a least cost answer node.  $I(1)/I(n) \leq n$  for n > 1.

**Proof**: From the proof of Theorem 2, we know that I(1) = m where m is the number of critical nodes. Since all critical nodes must become E-nodes before the branch-and-bound algorithm can terminate,  $I(n) \ge m/n$ . Hence,  $I(1)/I(n) \le n$ . []

When  $1 < n_1 < n_2$  and g(N) is restricted as above,  $I(n_1)/I(n_2)$  can exceed  $n_2/n_1$  but cannot exceed  $n_2$ .

**Theorem 7**: Assume that  $g(N) \neq f^*$  whenever N is not a least cost answer node. Let  $1 < n_1 < n_2$ . The following are true:

- (1)  $I(n_1)/I(n_2) \le n_2$ .
- (2) There exists a problem instance for which  $I(n_1)/I(n_2) > n_2/n_1$ .

**Figure 3**: Instance for Theorem 3

**Proof**: (1) From Theorems 2 and 6, we immediately obtain:

$$\frac{I(n_1)}{I(n_2)} = \frac{I(n_1)}{I(1)} * \frac{I(1)}{I(n_2)} \le n_2.$$

(2) For simplicity, we assume that  $k = n_2 / n_1$  is an integer. Consider the state space tree of Figure 6. The g() value of all nodes other than the one representing the least cost answer is less than  $f^*$ . The number inside (outside) a node is the iteration in which it is the E-node when  $n_1$  ( $n_2$ ) processors are used. We see that  $I(n_1) = n_2(k+1) + 1$  and  $I(n_2) = n_2 + 2$ . Hence,

$$\frac{I(n_1)}{I(n_2)} = \frac{n_2k + n_2 + 1}{n_2 + 2} > k. \quad []$$

## 3. Experimental Results

In order to determine the frequency of anomalous behavior described in the previous section, we simulated a parallel branch-and-bound with  $2^k$  processors for k = 0, 1, 2, ..., 9. Two test problems were used: 0/1-Knapsack and Traveling Salesperson. These are described below.

0/1-Knapsack:

In this problem we are given n objects and a knapsack with capacity M. Object i has associated with it a profit  $p_i$  and a weight  $w_i$ . We wish to place a subset of the n objects into the knapsack such that the knapsack capacity is not exceeded and the sum of the profits of the objects in the knapsack is maximum. Formally, we wish to solve the following problem:

maximize 
$$\sum_{i=1}^{n} p_i x_i$$
  
subject to 
$$\sum_{i=1}^{n} w_i x_i \le M, x_i \in \{0, 1\}.$$

Horowitz and Sahni [10] describe two state space trees that could be used to solve this problem. One results from what they call the fixed tuple size formulation. This is a binary tree such as the one shown in Figure 7(a) for the case n = 3. The other results from the variable tuple size formulation. This is an n-ary tree. When n = 3, the resulting tree is as in Figure 7(b). The bounding function used is the same as the one described in [10]. Since the bounding function requires that objects be ordered such that  $p_i/w_i \ge p_{i+1}/w_{i+1}$ ,  $1 \le i < n$ , we generated our test data by first generating random  $w_i$ s. The  $p_i$ s were then computed from the  $w_i$ s by using a random nonincreasing sequence  $f_1, f_2, ..., f_n$  and the equation  $p_i = f_i w_i$ . We generated 100 instances with n = 50 and 60 instances with n = 100. These 160 instances were solved using the binary state

**Figure 4**: Instance for Theorem 4

Figure 5: Instance for Theorem 5

space tree described above. (We also tried the n-ary state space tree but found that it would take several weeks of computer time to complete our simulation. The reason it will take so much time is that when n-ary state space trees are used a great number of nodes will be generated and the queue of live nodes will exceed the capacity of main memory and has to be moved to the secondary storage. In our program, it is time consumming to maintain a queue of live nodes that must be partly stored in secondary storage.)

**Table 1**: Experimental results (knapsack)

Table 1 gives the average values for I(p), I(1)/I(p) and I(p)/I(2p). From Table 1, we see that when n=50, I(1)/I(p) is significantly less than p for p>2. The observed improvement in performance is not as high as one might expect. Similarly, the ratio I(p)/I(2p) drops rapidly to 1 and is acceptable only for p=1 and 2 (see also Figure 8). In none of the 100 instances tried for n=50 did we observe anomalous behavior. I.e., it was never the case that I(p) < I(2p) or that I(p) > 2I(2p).

When n = 100, the ratio I(1)/I(p) is significantly less than p for p > 8 (see also Figure 9). Of the 60 instances run, 6 (or 10%) exhibited anomalous behavior. For all 6 of these there was at least one p for which I(p) > 2I(2p). There was only one case where I(p) < I(2p). The values of

# Figure 7

I(p), I(1)/I(p), and I(p)/I(2p) for these six instances is given in Table 2. It is striking to note the instance for which I(1)/I(2) = 14.6 and I(2)/I(4) = 0.15.

## The Traveling Salesperson Problem:

Here we are given an n vertex undirected complete graph. Each edge is assigned a weight. A *tour* is a cycle that includes every vertex (i.e., it is a Hamiltonian cycle). The *cost* of a tour is the sum of the weights of the edges on the tour. We wish to find a tour of minimum cost.

The branch-and-bound strategy that we used is a simplified version of the one proposed by Held and Karp [9]. Vertex 1 is chosen as the start vertex. There are n - 1 possibilities for the next vertex and n - 2 for the preceding vertex (assume n > 2). This leads to (n - 1)(n - 2) sequences of 3 vertices each. Half of these may be discarded as they are symmetric to other

Table 2: Data exhibiting anomalous behavior

expanded one vertex at a time using the set of vertices adjacent to the end of the path. A lower bound for the path  $(i_1, i_2, ..., i_k)$  is obtained by computing the cost of the minimum spanning tree for  $\{1, 2, ..., n\}$  -  $\{i_1, i_2, ..., i_k\}$  and adding an edge from each of  $i_1$ , and  $i_k$  to this spanning tree in such a way that these edges connect to the two nearest vertices in the spanning tree.

In our experiment with the traveling salesperson problem we generated 45 instances each having 20 vertices. The weights were assigned randomly. However, each edge had a finite weight with probability 0.35. Use of a much higher probability results in instances that take years of computer time to solve by the branch-and-bound method.

These 45 instances were solved using  $p = 2^k$ ,  $0 \le k \le 9$  processors. The average values of I(p), I(1)/I(p), and I(p)/I(2p) are tabulated in Table 3. As can be seen, for  $p \le 32$  the average

p	I(p)	$\frac{I(1)}{I(n)}$	$\frac{I(p)}{I(2n)}$	
1	3974	$\frac{I(p)}{1.000}$	1(2p) 1.996	
2	1989	1.996	1.990	
4	996	3.973	1.976	
8	500	7.849	1.943	
16	252	15.258	1.873	
32	129	28.685	1.753	
64	68	51.126	1.609	
128	39	85.378	1.417	
256	25	129.411	1.252	
512	19	177.459		

**Table 3**: Experimental results (traveling salesperson)

value of I(1)/I(p) is quite close to p and the average value of I(p)/I(2p) is quite close to 2 (see also Figure 10). No anomalies were observed for any of these 45 instances.

## 4. Conclusions

We have demonstrated the existence of anomalous behavior in parallel branch-and-bound. Our experimental results indicate that such anomalous behavior will be rarely witnessed in practice. Furthermore, there is little advantage to expanding more than k nodes in parallel. k will in general depend on both the problem and the problem size being solved. If we require I(p)/I(2p) to be at least 1.66, then for the knacksack problem with n = 50, k is between 4 and 8 whereas with n = 100 it is between 8 and 16 (based on our experimental results). For the traveling salesperson problem with 20 vertices k is between 8 and 16. If p is larger than k, then more effective use of the processors is made when they are divided into k groups each of size approximately p/k. Each group of processors is used to expand a single E-node in parallel. If s is the speedup obtained by expanding an E-node using q processors, then allocating q processors to each E-node and expanding only p/q E-nodes in parallel is preferable to expanding p E-nodes in parallel provided that sI(1)/I(p/q) > I(1)/I(p).
