On Optimal Deadlock Detection Scheduling

Yibei Ling, Member, IEEE, Shigang Chen, and Cho-Yu Jason Chiang

Abstract—Deadlock detection scheduling is an important, yet often overlooked problem that can significantly affect the overall performance of deadlock handling. Excessive initiation of deadlock detection increases overall message usage, resulting in degraded system performance in the absence of deadlocks, while insufficient initiation of deadlock detection increases the deadlock persistence time, resulting in an increased deadlock resolution cost in the presence of deadlocks. The investigation of this performance trade-off, however, is missing in the literature. This paper studies the impact of deadlock detection scheduling on the overall performance of deadlock handling. In particular, we show that there exists an optimal deadlock detection and resolution algorithms being used, as well as the rate of deadlock formation, denoted as λ . For the best known deadlock detection and resolution algorithms, we show that the asymptotically optimal frequency of deadlock detection scheduling that minimizes the overall message overhead is $\mathcal{O}((\lambda n)^{1/3})$ when the total number *n* of processes is sufficiently large. Furthermore, we show that, in general, fully distributed (uncoordinated) deadlock detection scheduling.

Index Terms—Deadlock detection scheduling, deadlock formation rate, deadlock persistence time.

1 INTRODUCTION

THE distributed deadlock problem [8], [20], [16], [26], [11], [14] arises from resource contention introduced by concurrent processes in distributed computational environments. It has received a great deal of attention in different areas such as distributed computing theory [22], [26], [9], distributed database [17], [14], [8], [10], [11], and parallel and distributed simulation [2], [28], [21]. A deadlock is a persistent and circular-wait condition, where each process involved in a deadlock waits indefinitely for resources held by other processes while holding resources needed by others. As a result, none of the processes waiting for needed resources can continue computation any further without obtaining the waited-for resources. A deadlock has an adverse performance effect that offsets the advantages of resource sharing and processing concurrency.

There are three common strategies for dealing with the deadlock problem: *deadlock prevention, deadlock avoidance,* and *deadlock detection and resolution.* It is a long-held consensus that both the deadlock prevention and deadlock avoidance strategies are conservative and less feasible in handling the deadlock problem in general, whereas the deadlock detection/resolution strategy is widely accepted as an optimistic and feasible solution to the deadlock problem because of its exclusion of the unrealistic assumption about resource allocation requirements of the processes [10], [16], [26], [7], [27]. The central idea behind the deadlock detection and resolution strategy is that it does not preclude the possibility of deadlock occurring but leaves the burden

of minimizing the adverse impact of deadlock to deadlock detection and resolution mechanisms. Under this scheme, the presence of deadlocks is detected by a periodic initiation of a deadlock detection algorithm and then resolved by a deadlock resolution algorithm [31], [27], [7].

Despite significant performance improvement in the past, deadlock detection remains a costly operation [26], [11], [19]. It requires dynamical maintenance of wait-forgraph (WFG) that reflects the runtime wait-for dependency among distributed processes and performs a graph analysis to detect the presence of deadlocks. There is a substantial trade-off between the cost of deadlock detection and that of deadlock resolution [26], [16], [23]. An initiation of deadlock detection consumes runtime system and network resources which are basically pure overheads when no deadlock is present [26], [19]. Excessive initiation of deadlock detection would reduce the deadlock resolution cost, but result in system performance degradation in the absence of deadlock, while infrequent deadlock detection would be accompanied by increased deadlock size, resulting in an increased deadlock resolution cost in the presence of deadlocks [23], [16], [15], [1]. It is evident that a *deadlock detection scheduling* is one of the key factors affecting the overall system performance of deadlock handling. Nevertheless, to the best of our knowledge, this subject is generally missing in the literature.

This paper investigates the optimal deadlock detection scheduling. We study how to best schedule deadlock detections so as to minimize the long-run mean average cost of deadlock handling. We formulate this problem by introducing a generic cost model (utility metric) and use this cost model to establish a connection between deadlock detection and deadlock resolution costs, in relation to the rate of deadlock formation. We show that there exists a unique optimal deadlock detection frequency that yields the minimum long-run mean average cost. Moreover, our result indicates that the asymptotically optimal frequency of deadlock detection that minimizes the message overhead

is $O((\lambda n)^{1/3})$, when the number *n* of processes in the system is sufficiently large. In addition, we prove that a fully distributed (uncoordinated) detection scheduling cannot be performed as efficiently as its centralized counterpart (coordinate scheduling).

The rest of this paper is organized as follows: Section 2 contains a brief summary of the distributed deadlock detection and resolution algorithms. Section 3 gives the notions and definitions. Section 4 provides the detailed mathematical analysis and proves the existence and uniqueness of an optimal detection frequency. The determination of the optimal deadlock detection frequency, its asymptotic relation with the number of processes in a distributed system, and the impact of random detection scheduling upon the long-run mean average cost of deadlock handling are presented. In Section 5, the main contribution of this paper is highlighted and possible future work is discussed.

2 BACKGROUND

In this section, we provide a brief summary of the worstcase analysis of existing distributed detection algorithms of generalized deadlocks and deadlock resolution algorithms since some results will be used later on. We also touch on Gray et al.'s simulation model [8] as well as Massey's formulation [20].

We restrict our discussion to distributed detection and resolution algorithms. The references [10], [12], [13], [11], [14], [16] provide excellent gateways to the state of the art in this area for the generalized resource request model. In the following, we give a brief summary of the worst-case performance of the existing distributed detection algorithms.

Table 1 summarizes the worst-case complexities of distributed deadlock detection algorithms [3], [30], [12], [14], where *n* is the total number of processes, *e* is the number of edges, *d* is the diameter, and *l* is the number of sink nodes of the WFG. The distributed detection algorithm for generalized deadlocks by Kshemkalyni and Singhal [14] is the clear winner among the algorithms listed in Table 1. Their algorithm has achieved a message complexity of 2e and a time complexity of 2d, which are believed to be optimal. Since e = n(n - 1) and d = n in the worst-case analysis, the worst-case message complexity and time complexity thus can be written as $2n^2$ and 2n, respectively.

Although deadlock detection and deadlock resolution are often discussed separately, the latter is as important as the former [10], [26], [12], [7], [27], [32], [16]. The primary issue of deadlock resolution [15], [16], [17] is to selectively abort a subset of processes involved in the deadlock so as to minimize the overall abortion cost [19], [26], [27], [7]. This is

TABLE 2 Distributed Deadlock Resolution Algorithms

often referred to as the *minimum abort set problem*. These victim (aborted) processes must cancel all pending requests and release all the acquired resources in order to avoid false deadlock detection and resolution [26], [12], [7]. The abortion cost thus includes 1) the sending of cancel messages to those resources and 2) the sending of reply messages to all the waiting processes that are currently being blocked for the resources held by the aborted processes. One noteworthy point is that these waiting processes. To further reduce the abortion cost, checkpointing is sometimes introduced to prevent the victim processes from being rolled back from scratch [18].

In addition, it is possible that more than two processes can independently detect the same deadlock. If each process that detects a deadlock resolves it, then the deadlock resolution will be highly inefficient and will result in subsequent false deadlock detection and deadlock resolution [26], [7], [13], [15]. Therefore, only one process should be selected for resolving a deadlock, which in turn requires that the initiations of deadlock resolution algorithm in different sites be coordinated. Such a coordination for safe deadlock resolution comes at an additional communication cost in message exchange [7].

Generally, deadlock resolution cost is measured either in terms of time complexity [6], [17], [27] or in terms of message complexity [15], [16], [7]. The complexity of resolution algorithms is summarized in Table 2, where n is the total number of processes, m the number of processes having the priorities greater than deadlocked processes, N_r the number of resources, and n_D the size of a deadlock. Note that the message complexities are not given in [17], [27].

By transforming the problem of deadlock resolution into a minimum vertex cut problem, Chen et al.'s algorithm [5] can identify an optimal set of victim processes to be aborted, with the properly selected abortion cost to avoid the starvation and livelock problems. The main feature of Terekhov and Camp's algorithm is to take the number of resources into account. The deadlock resolution algorithm proposed by Mendivil et al. [7] uses a probe-based approach, with a focus on the safety aspect of deadlock resolution. The novelty of this algorithm is to use an additional round of message exchanges to gather the information needed for efficient resolution after deadlocks are detected. The algorithm uses special messages known as probes to travel in the opposite direction of the edges in AWFG (asynchronous wait-for graph) and then chooses the lowest priority process of each detected cycle as a victim process to be aborted, hence avoiding the livelock and starvation problems. This deadlock resolution algorithm [7] excels in the use of formal methods to prove the correctness and in its fine-granular analysis of

Past research has been primarily aimed at minimizing the complexities (costs) of the deadlock detection and resolution algorithms. Although deadlock detection scheduling (particularly how frequently deadlock detection should be performed) has a significant impact on the overall performance of deadlock handling in practice, it is not explicitly studied but, rather, implicitly reflected in the description of deadlock detection algorithms, without a clear guideline. For instance, in [10], [26], [14], [16], [19], [4], [5], the authors stated that a deadlock detection is initiated when a deadlock is suspected. Other works [23], [11] suggested that it would be highly inefficient if deadlock detection is performed whenever a process/transaction becomes blocked.

The performance of deadlock handling not only depends on the per-detection cost of the deadlock detection algorithm, but also on how frequently the deadlock detection algorithm is executed [11], [23], [19]. The choice of deadlock detection frequency presents a trade-off between deadlock detection cost and deadlock resolution cost [10], [26], [23], [16], [11]. Park et al. [23] pointed out that the reduction of deadlock resolution cost can be achieved at the expense of deadlock detection cost. Krivokapic et al. [11] showed in their simulation study that the path-pushing algorithm (one type of deadlock detection algorithm) is highly sensitive to the frequency of deadlock detection. Gray et al. [8] showed that the probability of a transaction waiting for a lock request is rare. They used a "straw-man analysis" in their simulation model that agreed well with the observation on several data management systems. Massey [20] formulated a probabilistic model that gave an analytic justification for the simulation results reported in [8], showing that the probability of deadlock grows linearly with respect to the number of transactions and grows in the fourth power of the average number of resources required by transactions.

To the best of our knowledge, only a few papers [8], [16], [27], [5], [26], [19], [6] mentioned deadlock detection scheduling, but under a different context from this paper. The idea of relating deadlock recovery cost to deadlock persistence time and identifying an optimal deadlock detection frequency that minimizes the long-run mean average cost from the perspective of deadlock handling has not been considered before.

3 DEADLOCK PERSISTENCE TIME AND DEADLOCK RECOVERY COST

In this section, we first give the following definitions in order to simplify problem formulation:

Definition 1. A deadlock refers to a circular-wait condition where a set of processes waits indefinitely for resources from each other. A blocked process (a process in a deadlock) refers to the process that waits indefinitely on other processes to progress. Deadlock size refers to the total number of blocked processes involved in the deadlock. Blocked processes can be decomposed into two categories: *deadlocked* and *transitively blocked* processes [16]. Deadlocked processes belong to a cycle in the WFG, while a transitively blocked process refers to one that waits for the resources held by other processes but does not belong to any cycle in the WFG.

Definition 2. Two deadlocks are said to be independent of each other if they don't share any deadlocked process.

The independence of deadlock occurrence can be justified by the wide acceptance of large-scale distributed systems and adoption of fine-granularity locking mechanism such as *semantic locking* [24], [11] and record-granularity locking [24]. After decades of research and development, large-scale distributed systems allow resource sharing among hundreds or even thousands of sites across a network [24], [11]. The fine-granular locking mechanisms enable a higher degree of parallelism. Large-scale resource distribution and fine-granularity of locking make deadlocks likely to form independently.

Now, we are in a position to introduce the notion of deadlock persistence time, which serves as a basis for our problem formulation. Let $S = \{S_1, S_2, \dots\}$ be the time instants at which independent deadlocks initially occur, i.e., the *i*th deadlock forms at time S_i .

Definition 3. The persistence time of the *i*th deadlock with respect to time t, denoted by $t_p(t, S_i)$, is

$$t_p(t, S_i) = \begin{cases} t - S_i, & t > S_i; \\ 0, & t \le S_i. \end{cases}$$

The function $t_p(t, S_i)$ represents the time interval between the present time and the time at which the deadlock is initially formed. It grows linearly until the deadlock is resolved. The notion of deadlock persistence time in spirit is similar to that of *deadlock latency* or *deadlock duration* in [16], [15].

Once a deadlock is formed, other processes requesting resources currently held by the blocked processes in the deadlock (including deadlocked and transitively blocked processes) will be blocked forever unless the deadlock is resolved. As a result, each deadlock acts as an attractor to trap more processes into it. As the deadlock persistence time increases, the size of the deadlock (the total number of processes involved in the deadlock) keeps growing [26], [9], [16], [15], which in turn increases the deadlock resolution cost.

This dependency of deadlock resolution cost upon deadlock persistence time is illustrated in the example in Fig. 1. At time = 1, there are three circularly deadlocked processes and two transitively blocked processes. At time = 2, there are seven circularly deadlocked processes. The graphs Fig. 1a and Fig. 1b represent two snapshots in the wait-for graph, showing that the deadlock size (including both deadlocked and transitively-blocked processes) grows with the deadlock persistence time. Intuitively, a deadlock resolution algorithm will have to explore the entire deadlock in order to identify the least costly set of victim processes to be aborted. The intrinsic dependency of deadlock size (and, thus, deadlock resolution cost) upon deadlock persistence time was observed by Singhal et al. [26], [13], Villadangos et al. [29],

Fig. 1. Increasing deadlock size with deadlock persistence time: (a) time = 1 and (b) time = 2.

Lee and Kim [16], [15], Krivokapic et al. [11], Lin and Chen [17], and Park et al. [23].

Throughout this paper, we use *n* to denote the total number of processes in a distributed system and $n_D(.)$ to denote the size of a deadlock. Consider an arbitrary deadlock. Its size is a function of deadlock persistence time t_p , denoted as $n_D(t_p)$. The deadlock size $n_D(t_p)$ by nature is a discrete staircase function that jumps by one whenever a new process becomes transitively blocked by the deadlocked processes. To facilitate our mathematical analysis, we will treat $n_D(t_p)$ instead as a continuous, increasing function which is an approximation of the staircase one.

The deadlock size function $n_D(t_p)$ has the following mathematical properties: 1) $n_D(0) = 0$, 2) monotonicity: $n'_D(t_p) > 0$, $t_p \ge 0$, and 3) bounded: $n_D(\infty) \le n$, where $n'_D(t_p)$ is the derivative of $n_D(t_p)$. The first property refers to the initial deadlock size at $t_p = 0$ is zero. The second property reflects the fact that the number of blocked processes in the deadlock increases monotonically with deadlock persistence time t_p and the third property indicates that the eventual deadlock size is bounded by the total number of distributed processes. For the sake of easy presentation, we drop the subscript p hereafter.

Now, let's revisit the message complexity achieved by the deadlock resolution algorithm proposed by Mendivil et al. [7], which is $O(mn_D^2) = O(nn_D^2)$, where *m* is the number of deadlocked processes having priority values greater than those of the deadlocked processes. Notice that the deadlock size, n_D , is a function of deadlock persistence time. To make this dependency concrete, the message overhead can be written as $cnn_D^2(t)$ for some constant *c*. This result will be used later to derive the optimal frequency of deadlock detection scheduling.

4 MATHEMATICAL FORMULATION

In this section, we begin with a generic cost model that accounts for both deadlock detection and deadlock resolution, which is independent of deadlock detection/resolution algorithms being used. We then prove the existence and the uniqueness of an optimal deadlock detection frequency that minimizes the long-run mean average cost in terms of the message complexities of the best known deadlock detection/resolution algorithms.

In this paper, we choose the message complexity as the performance metric for measuring the detection/resolution cost. The reason for choosing message complexity is that communication overhead is generally a dominant factor that affects the overall system performance in a distributed system [26], [10], [13], [14], as compared with processing speed and storage space. Note that the worst-case message complexity can normally be expressed as a polynomial of n. Per deadlock detection cost is denoted as C_D . The resolution cost for a deadlock is denoted as $C_R(t)$, which is a function of the deadlock persistence time t. In general, the resolution cost is a polynomial of $n_D(t)$. For example, the deadlock resolution cost for Mendivil et al.'s algorithm [7] is $cnn_D^2(t)$ because $n_D(t)$ is a monotonically increasing function of deadlock persistence time. $C_R(t)$ is also monotonically increasing with deadlock persistence time. We assume that deadlock formation follows a Poisson process for two reasons: First, the Poisson process is widely used to approximate a sequence of events that occur randomly and independently. Second, it is due to the mathematical tractability of the Poisson process, which allows us to characterize the essential aspects of complicated processes while making the problem analytically tractable.

The following theorem presents the long-run mean average cost of deadlock handling in connection with the rate of deadlock formation and the frequency of deadlock detection:

Theorem 1. Suppose deadlock formation follows a Poisson process with rate λ . The long-run mean average cost of deadlock handling, denoted by C(T), is

$$C(T) = \frac{C_D}{T} + \frac{\lambda \int_0^T C_R(t)dt}{T},$$
(1)

where the frequency of deadlock detection scheduling is 1/T.

Proof. Let $\{X_i, i \ge 1\}$ be the interarrival times of independent deadlock formations, where random variables $X_i, i \ge 1$ are independent and exponentially distributed with mean $1/\lambda$. Define $S_0 = 0$ and $S_n = \sum_{i=1}^n X_i$, where S_n represents the time instant at which the *n*th independent deadlock occurs.

Let $N(t) = \sup\{n : S_n \le t\}$ represent the number of deadlock occurrences within the time interval (0, t]. The long-run mean average cost is

$$\lim_{t \to \infty} \frac{E(\text{random cost in } (0, t])}{t}, \qquad (2)$$

where *E* is the expectation function. In order to associate this cost with the deadlock detection frequency (1/T), we partition the time interval (0, t] into nonoverlapping subintervals of length *T*. Let $\xi_k(T)$ be the cost of deadlock handling on the subinterval $((k - 1)T, kT], k > 0. \xi_k(T)$ is a random variable. According to the stationary and independent increments of the Poisson process [25], $E(\xi_i(T)) = E(\xi_j(T)), i \neq j$. The long-run mean average cost becomes

$$C(T) = \lim_{t \to \infty} \frac{E(\operatorname{random cost in}(0, t])}{t} = \lim_{t \to \infty} \frac{E(\sum_{k=0}^{\lfloor t \rfloor} \xi_k(T))}{t}$$
$$= \lim_{t \to \infty} \frac{E(\lfloor \frac{t}{T} \rfloor \xi_1(T))}{t} = \frac{E(\xi_1(T))}{T},$$
(3)

where |x| is the floor function in x.

The cost $\xi(T)$ on interval (0,T] is the sum of a deadlock detection cost C_D and a deadlock resolution cost for those deadlocks independently formed within the interval (0,T]. For the *i*th deadlock formed at time $S_i \leq T$, the resolution cost $C_R(T - S_i)$ is a function of the deadlock persistence time $T - S_i$. Hence, the accrued total cost over (0,T] is

$$\xi(T) = C_D + \sum_{i=1}^{N(T)} C_R(T - S_i) I_{\{N(T) > 0\}},$$
(4)

where I_{θ} is the indicator function whose value is 1 (or 0) if predicate θ is true (or false). Among that, the deadlock resolution cost on interval (0, T] is

$$\sum_{i=1}^{N(T)} C_R(T-S_i) I_{\{N(T)>0\}} = \sum_{i=1}^{\infty} C_R(T-S_i) I_{\{S_i \le T\}}, \quad (5)$$

$$E(C_R(T-S_i)I_{\{S_i \le T\}}) = \int_0^T C_R(T-t)f_i(t)dt, \qquad (6)$$

where $f_i(t)$ is the probability density function of S_i which follows the gamma distribution given below:

$$f_i(t) = \frac{\lambda^i}{(i-1)!} t^{i-1} e^{-\lambda t}, t > 0.$$
(7)

Substituting (7) into (6) gives rise to

$$E(C_R(T-S_i)I_{\{S_i \le T\}}) = \int_0^T C_R(T-t)\frac{\lambda^i}{(i-1)!}t^{i-1}e^{-\lambda t}dt.$$
(8)

The expected total resolution cost over the time interval (0, T] is

$$E\left(\sum_{i=1}^{N(T)} C_R(T-S_i)I_{\{N(T)>0\}}\right)$$

= $\sum_{i=1}^{\infty} \int_0^T C_R(T-t) \frac{\lambda^i t^{i-1}}{(i-1)!} e^{-\lambda t} dt$
= $\int_0^T C_R(T-t)\lambda e^{-\lambda t} \left(\sum_{i=1}^{\infty} \frac{(\lambda t)^{i-1}}{(i-1)!}\right) dt = \lambda \int_0^T C_R(T-t) dt$
= $\lambda \int_0^T C_R(t) dt.$ (9)

Combining (3), (4), and (9) yields

$$C(T) = \frac{E(\xi_1(T))}{T} = \frac{C_D}{T} + \frac{\lambda \int_0^T C_R(T-t)dt}{T}$$

= $\frac{C_D}{T} + \frac{\lambda \int_0^T C_R(t)dt}{T}.$ (10)

Theorem 1 is thus established.

Theorem 1 is mainly concerned with the impact of deadlock detection frequency and deadlock formation rate on the long-run mean average cost of overall deadlock handling. It is independent of the choice of deadlock detection/resolution algorithms. The following corollary is an immediate consequence of Theorem 1:

Corollary 1. The long-run mean average cost of deadlock handling is proportional to the rate of deadlock formation λ .

Proof. The proof is straightforward and, thus, omitted. \Box

Theorem 1 and Corollary 1 state that the overall cost of deadlock handling is closely associated not only with perdeadlock detection cost and aggregated resolution cost, but also with the rate of deadlock formation, λ . In the following lemma, we will show the existence and uniqueness of asymptotic optimal frequency of deadlock detection when deadlock resolution is more expensive than a deadlock detection in terms of message complexity.

Lemma 1. Suppose that the message complexity of deadlock detection is $\mathcal{O}(n^{\alpha})$, and that of deadlock resolution is $\mathcal{O}(n^{\beta})$. If $\alpha < \beta$, there exists a unique deadlock detection frequency $1/T^*$ that yields the minimum long-run mean average cost when n is sufficiently large.

Proof. Differentiating (1) yields

$$C'(T) = -\frac{C_D}{T^2} + \frac{\lambda C_R(T)}{T} - \frac{\lambda \int_0^T C_R(t) dt}{T^2}.$$
 (11)

Define a function $\varphi(T)$ as follows:

$$\varphi(T) \equiv T^2 C'(T) = -C_D + \lambda T C_R(T) - \lambda \int_0^T C_R(t) dt. \quad (12)$$

Notice that C'(T) and $\varphi(T)$ share the same sign. Differentiating $\varphi(T)$, we have

$$\varphi'(T) = \lambda T C'_R(T). \tag{13}$$

Because $C_R(T)$ is a monotonically increasing function, $C'_R(T) > 0$, which means $\varphi'(T) > 0$. Therefore, $\varphi'(T)$ is also a monotonically increasing function. $C_R(T) - C_R(t) \ge 0$ holds iff $T \ge t$. For any given $0 < \xi < T$, it has

$$TC_{R}(T) - \int_{0}^{T} C_{R}(t)dt = \int_{0}^{T} (C_{R}(T) - C_{R}(t))dt$$

>
$$\int_{0}^{\xi} (C_{R}(T) - C_{R}(t))dt$$

>
$$\int_{0}^{\xi} (C_{R}(T) - C_{R}(\xi))dt$$

=
$$\xi (C_{R}(T) - C_{R}(\xi)).$$
 (14)

Applying (14) to (12), we have

$$\varphi(T) = -C_D + \lambda(TC_R(T) - \int_0^T C_R(t)dt)$$

> $-C_D + \lambda\xi(C_R(T) - C_R(\xi)).$ (15)

We further have

$$\varphi(T) > -C_D + \lambda \xi C_R(T) \left(1 - \frac{C_R(\xi)}{C_R(T)} \right) = -C_D + \lambda \xi C_R(T) \theta,$$
(16)

where $\theta = (1 - C_R(\xi)/C_R(T))$ and $0 < \theta < 1$ since $C_R(T)$ is monotonically increasing. Substituting $C_D = c_1 n^{\alpha}$ and $C_R(\infty) = c_2 n^{\beta}$ in (16), we obtain

$$\lim_{T \to \infty} \varphi(T) > -c_1 n^{\alpha} + \lambda \xi \theta c_2 n^{\beta}.$$
(17)

Since $\alpha < \beta$, $\lim_{T\to\infty} \varphi(T)$ is asymptotically dominated by the term $\lambda \xi \theta c_2 n^{\beta}$ when *n* is sufficiently large. Observe that $\varphi(0) = -C_D < 0$ and $\varphi(T)$ is monotonically increasing. By the intermediate value theorem, it must be true that there exists a unique T^* , $0 < T^* < \infty$, such that

$$\varphi(T) = T^2 C'(T) = \begin{cases} < 0, & 0 \le T < T \\ = 0, & T = T^* \\ > 0, & T > T^*. \end{cases}$$

It means that C(T) reaches its minimum at and only at $T = T^*$. The existence and the uniqueness of optimal deadlock detection interval $T^* = \arg(\min_{T>0} C(T))$ is proven.

To make the idea behind this derivation concrete, we apply the up-to-date results of deadlock detection/resolution algorithms. As discussed before, the best-known message complexity of a distributed deadlock detection algorithm is $2n^2$ [14] when it is written as a polynomial of n. The best-known message complexity of a deadlock resolution algorithm is $\mathcal{O}(nn_D^2)$ [7]. Therefore, $C_D = n^2$ and $C_R(t) = cnn_D^2(t)$, where c is a positive constant. Because the deadlock size $n_D(t)$ is always bounded by n, from (15) we have

$$\varphi(\infty) = \lim_{T \to \infty} \varphi(T) > -C_D + \lambda \xi (C_R(\infty) - C_R(\xi))$$

$$\approx -2n^2 + \lambda c \xi n^3.$$
(18)

Note that ξ is a fixed value that can be arbitrarily chosen. For a sufficiently large *n*, (18) becomes

$$\varphi(\infty) \approx \lambda c \xi n^3 > 0, \tag{19}$$

 $\varphi(0) = -C_D = -2n^2$. Because $\varphi(T)$ is monotonically increasing, there exists an optimal deadlock detection frequency $1/T^*$ such that $\varphi(T^*)$ and, thus, $C'(T^*)$ are zero, which minimizes the long-run mean average cost C(T) for deadlock handling.

The motivation behind the proof is that the cost per deadlock detection is fixed when the total number of processes in the distributed system is given, while the cost of deadlock resolution monotonically increases with deadlock persistence time. The resolution cost will eventually outgrow the detection cost if deadlocks persist. As we set the time interval T between any two consecutive detections longer, the detection cost becomes smaller due to less frequent executions of the detection algorithm, but the resolution cost becomes larger due to the growth in deadlock size. This implies that there exists a unique deadlock detection frequency $1/T^*$ that balances the two costs such that their sum is minimized. The condition that the asymptotic deadlock resolution cost, $C_R(\infty)$, is greater than the cost of deadlock detection, C_D , constitutes the natural mathematical basis to justify distributed deadlock detection algorithms.

We are now ready to state the asymptotically optimal frequency for deadlock detection based on the up-to-date results of distributed deadlock detection and resolution algorithms. Recall that the best-known message complexity for distributed deadlock detection algorithms is $2n^2$ [14] and that for deadlock resolution algorithms of $\mathcal{O}(nn_D^2)$ [7].

- **Theorem 2.** Suppose the message complexity for distributed deadlock detection is $2n^2$ and that for distributed deadlock resolution is $\mathcal{O}(nn_D^2(t))$. Then, the asymptotically optimal frequency for scheduling deadlock detections is $\mathcal{O}((\lambda n)^{1/3})$.
- **Proof.** Assume that the deadlock size function $n_D(t)$ is both differentiable and integrable.¹ Then, $n_D(t)$ can be expressed in the form of Maclaurin series as follows:

$$n_D(t) = \sum_{i=0}^{\infty} \frac{n_D^{(i)}(0)t^i}{i!} = \sum_{i=0}^{\infty} c_i t^i,$$
(20)

where $n_D^{(i)}(0)$ denote the *i*th derivative of the deadlock size function $n_D(t)$ at point zero and $c_i = n_D^{(i)}(0)/i!$.

By the properties of the deadlock size function $n_D(t)$, we have $n_D(0) = 0$ and $n'_D(0) > 0$. It can be easily verified that $c_0 = 0$ and $c_1 = n'_D(0) > 0$. The resolution cost $C_R(t)$ can be written as $cnn_D^2(t)$ for some constant *c*. By Theorem 1, the long-run mean average cost becomes

$$C(T) = \frac{2n^2}{T} + \lambda cn \frac{\int_0^T n_D^2(t)dt}{T}.$$
 (21)

Inserting (20) into (21), we have

$$C(T) = \frac{2n^2}{T} + \lambda cn^3 T^{-1} \int_0^T \left(\sum_{i=1}^\infty c_i t^i\right)^2 dt$$

= $\frac{2n^2}{T} + \frac{\lambda cn^3 \int_0^T (c_1 t + \sum_{i=2}^\infty c_i t^i)^2 dt}{T}.$ (22)

Through a lengthy calculation, (22) can be simplified as

$$C(T) = \frac{2n^2}{T} + c\lambda n^3 \left(\frac{c_1^2 T^2}{3} + \frac{2c_1 c_2 T^3}{4} \right) + c\lambda n^3 \left(\sum_{i=2}^{\infty} \sum_{j=2}^{\infty} \frac{c_i c_j T^{i+j}}{i+j+1} \right).$$
(23)

Taking a derivative of (23) with respect to T, we have

$$C'(T) = -\frac{2n^2}{T^2} + c\lambda n^3 \left(c_1^2 \frac{2T}{3} + \frac{3c_1 c_2 T^2}{2} \right) + c\lambda n^3 \left(\sum_{i=2}^{\infty} \sum_{j=2}^{\infty} \frac{c_i c_j (i+j) T^{i+j-1}}{i+j+1} \right).$$
(24)

By Lemma 1, there exists a unique optimal detection frequency $1/T^*$ when *n* is sufficiently large, such that $C(T^*) \leq C(T), T \in (0, \infty)$. We know that $C'(T^*) = 0$. Based on (24), we transform $C'(T^*) = 0$ to the following equation:

1. Recall that $n_D(t)$ is a continuous approximation function whose curves between "jumping points" can be chosen.

Fig. 2. Cost of deadlock handling versus detection interval (n: number of processes).

Fig. 3. Cost of deadlock handling versus deadlock formation rate λ .

$$\frac{1}{n} = \frac{c\lambda}{2} \left(\frac{2c_1^2(T^*)^3}{3} + \frac{3c_1c_2(T^*)^4}{2} + \sum_{i=2}^{\infty} \sum_{j=2}^{\infty} \frac{c_ic_j(i+j)(T^*)^{i+j+1}}{i+j+1} \right).$$
(25)

Only n, T^* , and λ are free variables and the rest are constants. By performing the Big-O reduction, we obtain

$$\frac{1}{n} = \Theta(\lambda((T^*)^3 + (T^*)^4 + (T^*)^5 + \ldots)).$$
(26)

When *n* is sufficiently large and T^* is sufficiently small, we have

$$\frac{1}{n} = \Theta\left(\lambda \frac{(T^*)^3}{1 - T^*}\right) = \mathcal{O}(\lambda (T^*)^3)$$

$$T^* = \Omega\left(\frac{1}{(\lambda n)^{1/3}}\right).$$
(27)

Therefore, the asymptotic optimal deadlock detection frequency $1/T^*$ is $\mathcal{O}((\lambda n)^{1/3})$.

As an illustration, we consider an example as follows: Let $C_R(t) = n^3(1 - \exp(-t))$, $C_D = n^2$. In accordance with Theorem 1, the long-run mean average cost of deadlock handling thus is written as

$$C(T) = \frac{n^2 + \lambda n^3 (T + \exp(-T) - 1)}{T}.$$
 (28)

Fig. 2 and Fig. 3 show log-log plots of a family of curves illustrating the dependence of long-run mean average cost of deadlock handling upon detection interval. The *x*-axis denotes the deadlock detection interval and the *y*-axis denotes the long-run mean average cost of deadlock handling.

In Fig. 2, we present plots of the deadlock detection interval and cost of deadlock handling under different total numbers of processes, 50, 100, 200, 500, and 1,000, respectively. Fig. 3 shows the relationship between the overall cost of deadlock handling and deadlock detection interval under the different deadlock formation rates, 1*s*, 1/30s, 1/60s, 1/90s, and 1/120s, respectively. Fig. 2 and Fig. 3 visualize convexity that suggests the existence of an optimal detection frequency, illustrating that the overall cost of deadlock handling increases with the total number of processes and deadlock formation rate.

A detailed calculation given in Table 3 shows that, as the number of processes in a distributed system increases, the

TABLE 3 Optimal Detection Interval versus # of Processes

# of Processes	Optimal Detection Interval $(\lambda = 1)$
50	0.214699(s)
100	0.148555(s)
200	0.103495(s)
500	0.064189(s)
1000	0.045402(s)
# of Processes	Optimal Detection Interval ($\lambda = 1/30$)
# of Processes 50	Optimal Detection Interval ($\lambda = 1/30$)2.0223(s)

# of Processes 50 100 200	Optimal Detection Interval ($\lambda = 1/30$) 2.0223(s) 1.0973(s) 0.6832(s)
# of Processes 50 100 200 500	Optimal Detection Interval ($\lambda = 1/30$) 2.0223(s) 1.0973(s) 0.6832(s) 0.3942(s)

optimal detection interval decreases, which is clearly in line with our theoretical analysis. In the sequel, we study the impact of coordinated versus random deadlock detection scheduling on the performance of deadlock handling. We consider two strategies of deadlock detection scheduling: 1) centralized, coordinated deadlock detection scheduling and 2) fully distributed, uncoordinated deadlock detection scheduling.

The centralized scheduling excels in its simplicity in implementation and system maintenance, but undermines the reliability and resilience against failures because one and only one process is elected as the initiator of deadlock detections in a distributed system. In contrast, the fully distributed scheduling excels in the reliability and resilience against failures because every process in the distributed system can independently initiate detections [15], without a single point of failure. However, due to the lack of coordination in deadlock detection initiation among processes, it presents a different mathematical problem from the centralized deadlock detection scheduling.

In the previous discussions, we have focused on the derivation of optimal frequency of deadlock detection in connection with the rate of deadlock formation and the message complexities of deadlock detection and resolution algorithms, assuming deadlock detections are centrally scheduled at a fixed rate of 1/T. To capture the lack of coordination in fully distributed scheduling, we will study the case where processes randomly, independently initiate the detection of deadlocks.

Let *n* be the number of processes in a distributed system and *T* be the optimal time interval between any two consecutive deadlock detections in the centralized scheduling. Consider a fully distributed deadlock detection scheduling, where each process initiates deadlock detection at a rate of 1/(nT) independently. Although the average interval between deadlock detections in the fully distributed scheduling remains *T* (the same as its centralized counterpart), the actual occurring times of those detections are likely to be nonuniformly spaced because the initiation of deadlock detection is performed by the processes in a completely uncoordinated fashion.

In the following, we will study the fully distributed (random) scheduling and compare it with the centralized scheduling. Consider a sequence of independently and identically distributed *iid* random variables $\{Y_i, i \ge 1\}$ defined on $(0, \infty)$ following certain distribution H. The sequence $\{Y_i, i \ge 1\}$ represents the interarrival times of deadlock detections initiated by the fully distributed scheduling and it is assumed to be independent of the arrival of deadlock formations. It is obvious that the centralized scheduling is a special case of the fully distributed scheduling.

Let \mathcal{H} be the family of all distribution functions on $(0, \infty)$ with finite first moment. Namely,

$$\mathcal{H} = \left\{ H : H \text{ is a CDF on } (0, \infty), \int_0^\infty \bar{H}(t) dt < \infty \right\}, \quad (29)$$

where $\bar{H}(t) \equiv 1 - H(t), \forall t \ge 0.$

The following theorem states that the lack of coordination in deadlock detection initiation by fully distributed scheduling will introduce additional overhead in deadlock handling. Therefore, the fully distributed scheduling in general cannot perform as efficiently as its centralized counterpart.

Theorem 3. Let C_H denote the long-run mean average cost under fully distributed scheduling with a random detection interval Y characterized by certain distribution $H \in \mathcal{H}$ with the mean of μ and C(T) denote the long-run mean average cost under centralized scheduling with a fixed detection interval T. Then,

$$C_H \ge C(T),\tag{30}$$

when $E(Y) = \mu = T$.

Proof. Since the sequence $\{Y_i, i \ge 1\}$ of interarrival times of deadlock detection is assumed to be independent of the Poisson deadlock formations, it is easy to see that the random costs over the intervals $(0, Y_1], (Y_1, Y_1 + Y_2], \ldots$ are *iid*. Using the same line of reasoning as in the proof of Theorem 1, the long-run mean average cost is expressed as

$$C_H = \frac{E(\text{random cost over } Y)}{E(Y)},$$
(31)

where $Y \in \mathcal{H}$ is a random variable representing the interval between two consecutive deadlock detections. Let $\xi(Y)$ be the random cost in the interval *Y*. The expected cost over the interval *Y* is given by

$$E(\xi(Y)) = E\{E[\xi(Y)|Y]\}$$

= $\int_0^\infty E(C_D + \sum_{n=1}^{N(y)} C_R(y - S_n)I_{\{N(y)>0\}})dH(y),$
(32)

where $S_n = \sum_{i=1}^n X_i$ denotes the time of the *n*th deadlock formation and N(y) represents the number of independent deadlocks that occurred in the time interval (0, y). It follows from the independence of $\{X_i, i \ge 1\}$ and $\{Y_i, i \ge$ 1} and from (32) that the long-run mean average cost is

$$C_{H} = \frac{E(\xi(Y))}{E(Y)} = \frac{\int_{0}^{\infty} (C_{D} + \int_{0}^{y} \lambda C_{R}(t) dt) dH(y)}{E(Y)}$$
$$= \frac{C_{D}}{E(Y)} + \frac{\int_{0}^{\infty} (\int_{t}^{\infty} \lambda C_{R}(t) dH(y)) dt}{E(Y)}$$
$$= \frac{C_{D}}{E(Y)} + \frac{\lambda \int_{0}^{\infty} C_{R}(t) \bar{H}(t) dt}{E(Y)}.$$
(33)

When $E(Y) = \mu = T$, meaning that the fixed deadlock detection interval *T* equals the mean value of the random detection interval *Y*, we compare the centralized (fixed) detection scheduling with the rate of 1/T with the fully distributed (random) one with the mean rate of $1/E(Y) = 1/\mu$. According to Theorem 1, the long-run mean average cost of fixed detection is given as

$$C(T) = \frac{C_D}{\mu} + \frac{\lambda \int_0^{\mu} C_R(t) dt}{\mu}.$$
 (34)

Subtracting (34) from (33) yields

$$C_{H} - C(T) = \frac{\lambda}{\mu} \left\{ \int_{0}^{\infty} C_{R}(t)\bar{H}(t)dt - \int_{0}^{\mu} C_{R}(t)dt \right\}$$
$$= \frac{\lambda}{\mu} \left\{ \int_{\mu}^{\infty} C_{R}(t)\bar{H}(t)dt - \int_{0}^{\mu} C_{R}(t)H(t)dt \right\}$$
$$\geq \frac{\lambda}{\mu} \left\{ C_{R}(\mu) \int_{\mu}^{\infty} \bar{H}(t)dt - C_{R}(\mu) \int_{0}^{\mu} H(t)dt \right\}$$
$$= \frac{\lambda C_{R}(\mu)}{\mu} \left\{ \int_{\mu}^{\infty} \bar{H}(t)dt - \int_{0}^{\mu} (1 - \bar{H}(t))dt \right\}$$
$$= \frac{\lambda C_{R}(\mu)}{\mu} \left\{ \int_{0}^{\infty} \bar{H}(t)dt - \mu \right\} = 0.$$
(35)

Hence, we have

$$C_H \ge C(T). \tag{36}$$

П

It can be seen from (36) that $C_H \ge C(T)$ and the equality holds if and only if Y is a degenerate random variable when Prob(Y = T) = 1. Theorem 3 asserts that the fully distributed (random) deadlock detection scheduling in general results in an increased overhead in overall deadlock handling.

5 CONCLUSION

Deadlock detection scheduling is an important, yet often overlooked aspect of distributed deadlock detection and resolution. The performance of deadlock handling not only depends upon per-execution complexity of deadlock detection/resolution algorithms, but also depends fundamentally upon deadlock detection scheduling and the rate of deadlock formation. Excessive initiation of deadlock detection results in an increased number of message exchange in the absence of deadlocks, while insufficient initiation of deadlock detection incurs an increased cost of deadlock resolution in the presence of deadlocks. As a result, reducing the per-execution cost of distributed deadlock detection/resolution algorithms alone does not warrant the overall performance improvement on deadlock handling. The main thrust of this paper is to bring an awareness to the problem of deadlock detection scheduling and its impact on the overall performance of deadlock handling. The key element in our approach is to develop a timedependent model that associates the deadlock resolution cost with the deadlock persistence time. It assists the study of time-dependent deadlock resolution cost in connection with the rate of deadlock formation and the frequency of deadlock detection initiation, differing significantly from past research that focuses on minimizing per-detection and per-resolution costs.

Our stochastic analysis, which solidifies the ideas presented in [10], [26], [23], [11], shows that there exists a unique deadlock detection frequency that guarantees a minimum long-run mean average cost for deadlock handling when the total number of processes in a distributed system is sufficiently large and that the cost of overall deadlock handling grows linearly with the rate of deadlock formation.

In addition, we study the fully distributed (random) deadlock detection scheduling and its impact on the performance of deadlock handling. We prove that, in general, the lack of coordination in deadlock detection initiation among processes will increase the overall cost of deadlock handling.

Theoretical results obtained in this paper could help system designers/practitioners to better understand the fundamental performance trade-off between deadlock detection and deadlock resolution costs, as well as the innate dependency of optimal detection frequency upon deadlock formation rate. However, there are still a lot of questions regarding how to use theoretical results to finetune the performance of a distributed system. Determination of the actual rate of deadlock formation and verification of the Poisson process are problems of great complexity that can be influenced by many known/unknown factors such as the granularity of locking, actual distribution of resource, process mix, and resource request and release patterns [26]. Tapping into system logging files and inferring the actual deadlock formation rate via data mining could provide an effective and feasible way to translate theoretical insights into actual system performance gain.

ACKNOWLEDGMENTS

The authors would like to thank Drs. Marek Rusinkiewicz, Wai Chen, and Ritu Chadh at Applied Research, Telcordia Technologies, for their constructive comments. They are grateful to the anonymous reviewers for critically reviewing the manuscript and for their truly helpful comments. Yibei Ling would like to especially thank Dr. Shu-Chan Hsu in the Department of Cell Biology and Neuroscience at Rutgers University for her encouragement and support. The material in this paper was presented in part at the 24th Annual ACM SIGACT-SIGOPS Symposium on Principles of Distributed Computing, 17-20 July 2005.
